APLV afectează 2% - 3% din copii in primul an de viață (1, 2, 3). De cele mai multe ori alergia este tranzitorie, majoritatea copiilor redobândindu-si toleranța la laptele de vacă (LV) în jurul vârstei de 3-4 ani. Copiii care au prezentat intoleranța la proteinele laptelui de vacă non-IgE şi-au redobândit mai repede toleranța la LV decât cei cu reacție mediată prin mecanism IgE, dar cu siguranța sunt şi alți factori necunoscuți până în prezent implicați în redobândirea toleranței la LV.

De asemenea, antecedentele de alergie alimentară reprezintă un factor de risc crescut în dezvoltarea altor boli alergice.

Studiile de specialitate arată că alergia alimentară creşte riscul pentru dezvoltarea astmului, rinitei, iar reacția la LV prin mecanism IgE creşte riscul apariției bolilor alergice. Deşi există date în literatura de specialitate cu privire la evoluția clinică şi dezvoltarea toleranței la proteinele laptelui de vacă, puține studii prospective au urmărit evoluția bolii de la naştere.

MATERIAL ŞI METODĂ

S-a efectuat un studiu prospectiv derulat pe o perioadă de 5 ani (ianuarie 2006- ianuarie 2010) pe un lot de sugari selectat timp de un an (2006) din două spitale din regiunea Moldovei, Spitalul Clinic de Urgență pentru Copii "Sf. Ioan" Galați, Compartimentul de gastroenterologie şi Spitalul Clinic de Urgență pentru Copii "Sf. Maria" Iaşi ce prezentau alergie la proteina laptelui de vacă. Alergia la proteina laptelui de vacă a fost confirmată prin testul de probă şi contraprobă ce reprezintă gold standardul în stabilirea acestui diagnostic.

Analiza a cuprins un număr de 71 copii cu vârste cuprinse între 0-12 luni ce prezentau un tablou clinic sugestiv pentru alergie la proteina laptelui de vacă, simptome digestive, asociate sau nu şi cu unele semne cutanate şi/sau respiratorii apărute după ingerarea laptelui de vacă, internați în două clinici din regiunea Moldovei. La copiii prezenți în studiu s-au identificat antecedente personale şi/sau familiare de atopie sau alergie. S-au urmărit datele anamnestico-clinice, evaluarea IgE specific, dieta de excludere şi proba de provocare.

Pentru analiza statistică a datelor am folosit o *SPSS 11.0*. Testele utilizate au fost specifice tipului de date analizate (cantitative, calitative) dintre care amintim testul Pearson χ^2, testul Fisher, testul t Student şi ANOVA ce au fost aplicate în comparații statistice. Curbele de supraviețuire au fost trasate utilizând metoda Kaplan-Meier, iar diferențele dintre grupuri au fost analizate cu ajutorul unui test log-rank.

În corelația multivariată s-a utilizat analiza logistică regresivă în care s-a studiat efectul mai multor factori cu privire la dezvoltarea toleranței la laptele de vacă. Datorită schimbărilor în IgE ca răspuns la proteina laptelui de vacă, au fost efectuate două analize: una folosind datele disponibi-

le la diagnostic şi alta folosind date disponibile după 12 luni de la diagnosticare. Factorii care sunt incluşi în studiu au fost antecedente familiale de atopie, fumatul parental, numărul de fraţi (0-1 sau 2) cu simptome alergice, prezenţa de animale cu blană.

Pozitivitatea IgE la proteina laptelui de vacă s-a măsurat la 12 luni de la diagnosticare. La copiii cu APLV am analizat efectele independente ale expunerii la lapte de vacă, istoria de APLV, antecedente familiale de atopie, prezenţa de animale cu blană, fumatul părinţilor, precum şi numărul de fraţi mai mari cu astm, rinoconjunctivita alergică, eczema atopică şi cu sensibilizare la alergeni.

Scopul studiului de a stabili evoluţia clinică a APLV precum şi a factorilor care favorizează apariţia toleranţei la LV. Copiii au fost urmăriţi până la dobândirea toleranţei la LV.

REZULTATE

În perioada analizată din cei 26.938 copiii internaţi în clinicile luate în studiu 4.485 au prezentat afecţiuni gastrointestinale dintre care 817 (18,22%) au fost alergii la proteina laptelui de vacă. Raportat la numărul total de internări incidenţa alergiei la proteina laptelui de vacă a fost de 3,03%. Prevalenţa sugarilor cu vârste mai mici de 12 luni ce prezintă alergie la proteina laptelui de vacă este de 8,69% din numărul total de copii diagnosticaţi cu APLV. Aceste rezultate sunt confirmate şi datele din literatură care menţionează faptul că simptomele alergiei alimentare se manifestă cu atât mai frecvent cu cât vârsta este mai mică (4).

Vârsta medie a fost de 7,57 luni ±2,73DS. La copiii incluşi in studiu, precum şi la lotul martor s-a urmărit frecventa apariţiei eczemei atopice, rinoconjunctivitei alergice, astmului, precum si a sensibilizării la alţi alergeni alimentari sau inhalatori. De asemenea, au fost urmăriţi factorii de risc implicaţi in apariţia manifestarilor alergice (formă digestivă, cutanată, respiratorie sau mixtă). Din lotul iniţial s-a analizat subgrupul copiilor care au dezvoltat toleranţă la proteina laptelui de vacă.

Rezultatele dozării IgE specific la proteina laptelui de vacă a evidenţiat faptul că 42 sugari (59,15%) au prezentat IgE negativ în timp ce 29 (40,85%) dintre aceştia prezentau IgE pozitiv. Pe parcursul urmăririi valorile IgE au prezentat modificări semnificative.

Distribuţia celor 71 copii cu APLV la momentul diagnosticului în funcţie de statutul de IgE specifice la LV este prezentată în figura următoare (fig. 1).

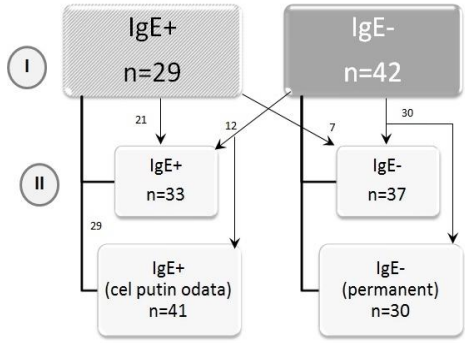

Fig. 1. Distribuţia cazurilor cu APLV la începutul tratamentului şi la 12 luni în funcţie de IgE specific

Rezultatele studiului evidenţiază faptul că numărul cazurilor cu valori pozitive ale IgE specific a scăzut, din cele 42 cazuri pozitive iniţial după 12 luni de urmărire 7 cazuri (24,14%) au devenit negative, iar la 12 (28,57%) din cele 29 cazuri cu IgE specific negativ statusul s-a schimbat. Se remarcă faptul că statusul IgE specific s-a schimbat la 19 cazuri (26,76%) în timp ce

41 cazuri (57,75%) au fost cel puțin odată IgE pozitiv, iar 30 cazuri au fost permanent negativ (42,25%).

Readministrarea laptelui de vacă s-a făcut la 12 luni după diagnostic la o vârsta medie de 1,6 ani (95%CI, 1,5 - 1,6 ani). Rezultatul testului a fost negativ (IgE s-a menținut negativ) la 37 cazuri (88,1%) iar la 12 (28,57%) copii IgE s-a pozitivat manifestându-se prin urticarie, exantem sau ambele, acestea fiind mai frecvente pentru copii cu IgE negativ – 35 cazuri comparativ cu frecvența la copiii la care IgE s-a pozitivat (94,59% *vs.* 16,67%, p=0,00271, 95% CI), în acest grup de copii mai des s-a întâlnit eczema atopică (41,67% - 5 cazuri vs. 10,81% - 4 cazuri, p=0,003) şi diaree (58,33% - 7 cazuri *vs.* 16,22% - 6 cazuri, p=0,037).

La prima probă de încărcare manifestările clinice au apărut la cei cu IgE prezent la aceştia predominând manifestările de tip: urticarie, exantem, wheezing recurent, în timp ce la cei care inițial IgE a fost negativ au fost mai des întâlnite: diaree, dermatita atopică, vărsături, falimentul creşterii.

Dezvoltarea toleranței

În sublotul cu IgE negativ toleranța la laptele de vacă a apărut semnificativ mai repede comparativ cu lotul cu IgE prezent. La vârsta de 5 ani toleranța s-a întâlnit la toți copii cu IgE (30 cazuri) negativ comparativ cu 70,73% în grupul copiilor cu IgE pozitiv (29 cazuri). La finalul studiului (vârsta medie 3,64 ani±1,35 SD) 5 cazuri (17,24%) cu IgE prezent inițial au rămas în continuare alergici la laptele de vacă aceştia prezentau semne clinice respiratorii şi cutanate. La vârsta medie de 1,6 ani 36 cazuri (48,65%) şi-au redobândit toleranța la proteina laptelui de vacă (PLV) (fig. 2). Sunt prezente diferențe semnificative în persistența APLV între grupul copiilor cu IgE + comparativ cu IgE- (Log-Rank test – p=0,1918, 95% CI).

Studiul factorilor de risc privind persistența manifestărilor alergice la proteina laptelui de vacă a fost realizată prin analiză multivariată ce a avut la bază regresia logistică, rezultatele fiind prezentat în tabelul următor. Au fost analizate antecedentele familiare de atopie, prezența de animale cu blană, fumatul părinților, precum şi numărul de frați cu manifestări alergice, eczema atopică şi cu sensibilizare la alergeni (tab. I).

TABELUL I

Estimarea parametrilor de şansă şi risc ai persistenței manifestărilor alergice

	Valoare Estimată - OR	*95% Interval de confidență*	
		Minim	**Maxim**
IgE pozitiv	4,54	2,08	6,87
Antecedente familiare de atopie	2,26	1,26	4,06
Fumat parenteral	1,19	1,29	2,71
Numărul fraților alergici	1,05	0,85	1,97
Prezența animalelor cu blană	1,24	0,73	2,06

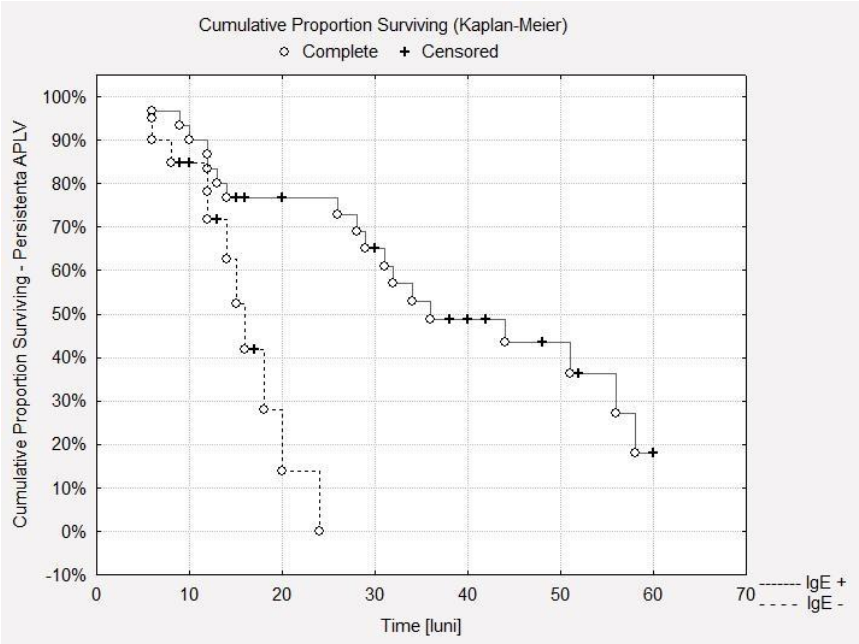

Fig. 2. Curba Kaplan-Meier privind persistența APLV în funcție de statusul IgE

DISCUȚII

Reacția de tip IgE la laptele de vacă crește riscul pentru a dezvolta persistență în APLV, iar copiii din acest grup au avut o vârsta semnificativ mai mare în momentul redobândirii toleranței la proteina laptelui de vacă. În același timp copiii cu IgE negativ și-au redobândit toleranța la vârsta de 5 ani. Am observat că dezvoltarea tardivă a sensibilizării tip IgE (la 12 luni după proba de încărcare) ar putea prezice persistența APLV după vârsta de 2 ani. Apariția anticorpilor IgE specifici pentru LV poate fi tardiva comparativ cu momentul apariției manifestarilor clinice. Creșterea tranzitorie a IgE alimentare specifice este relativ frecventă, dar numai sensibilizarea persistentă la alergenii alimentari crește riscul apariției manifestărilor respiratorii, sugerând ideea ca sensibilizarea tranzitorie este diferită de sensibilizarea persistentă. În momentul redobândirii toleranței un număr semnificativ (17.24%) din cei cu manifestări clinice de toleranță la LV vor rămâne totuși sensibilizați la proteina laptelui de vacă.

Urticaria ca simptom la proba de încărcare cu LV este un factor de risc pentru persistenta APLV până la vârsta de 2 ani. Alte studii nu au raportat o relație între simptomele clinice și vârsta de redobândire a toleranței la LV (5). Sensibilizarea la ou este un factor predictiv important al dezvoltării tardive a alergiei (6,7). De asemenea, expunerea precoce la LV determină dezvoltarea tardivă a toleranței la LV. Astfel, expunerea scurtă sau inconstantă la cantități mici de LV este un factor de risc pentru dezvoltarea sensibilizării IgE la LV(8) Studiile la animale au arătat că vârsta expunerii și cantitatea de antigen influențează apariția toleranței (9). Copiii cu APLV mediata IgE prezintă un risc crescut pentru alte boli alergice decât cei IgE negativ. Durata sensibilizării la alergenii alimentari precum și la

alergenii inhalatori se corelează cu riscul dezvoltării astmului şi a rinitei alergice. În studiul nostru am observat că intensitatea sensibilizării la LV la 12 luni de urmărire este un factor predictiv pentru rata de redobândire a toleranței şi dezvoltarea tardivă a altor boli alergice. Studiul de față demonstrează faptul că nivelul crescut al IgE specific laptelui de vacă este un factor predictiv semnificativ pentru persistența APLV, aspecte menționate şi de alți autori (5,6).

CONCLUZII

Cei mai mulți copiii îşi redobândesc toleranța în timpul copilăriei, iar cei cu IgE negativ chiar la vârste mici. Majoritatea copiilor cu APLV au prezentat reacții mediate IgE la LV, iar aceştia prezintă un risc crescut pentru bolile alergice, sensibilizarea la alergenii alimentari şi inhalatori, precum şi APLV persistentă. Valoarea prognostică a sensibilizării IgE la laptele de vacă depinde de vârstă; determinarea la 12 luni de la diagnostic este un factor predictiv pentru persistența APLV.

APLV mediată IgE persistă adesea la copiii de vârsta şcolara şi este un factor de risc şi pentru alte atopii; APLV non–IgE, din contra, este o afecțiune tranzitorie a sugarului şi copilului mic.

INFECŢIA CU *CLOSTRIDIUM DIFFICILE*: NOI PROVOCĂRI

Egidia Miftode, Daniela Leca, Olivia Dorneanu
Universitatea de Medicină şi Farmacie "Gr. T. Popa" Iaşi.
Facultatea de Medicină
Spitalul Clinic de Boli Infecţioase

CLOSTRIDIUM DIFFICILE INFECTIONS: WHAT IS NEW? (Abstract): *C. difficile* is the most common infectious cause of healthcare-associated diarrhea but now is increasingly recognized as a cause of diarrhea in outpatients and persons without apparent health care contacts. Emergence and spread of new epidemic clones of *C. difficile* 027 (PCR-ribotype) and 078/126 (toxinotype) with increase toxin production, an aditional binary toxin and high level resistance to fluoroquinolones and increasing incidence of more rapidly progressive severe disease, require prompt clinical recognition and new tools to predict severity and to prevent recurrences. Although antibiotics are effective at inhibiting *C. difficile* and treating symptoms, these drugs could not reestablish normal bowel flora and the rate of recurrences is 25%. During the past years we assisted to an impressive search for new and more effective therapy that shoud be save, with low potential for the development of resistance, with low levels of systemic absorbtion and high levels of active drug in the colon and should be associated with a low rate of recurrence after treatment. By consequence, different approaches to the management of recurrent infections have been studied such as new antibiotics (fidaxomicin), human monoclonal antibodies against *C. difficile* toxins A and B, intravenous human immunoglobulin, active immunization, and probiotic therapy. **Key words**: CLOSTRIDIUM DIFFICILE, INFECTIONS, DIAGNOSIS, TREATMENT.

Clostridium difficile este principalul agent al diareei asociate îngrijirilor medicale, dar, odată cu creşterea numărului de genotipuri implicate în izbucnirile epidemice din spitale se pune problema unor surse externe care sunt importate din mediul comunitar în cel spitalicesc, situaţie similară cu cea a infecţiei cu *Stapphylococcus aureus*.

Creşterea incidenţei infecţiei cu *C. difficile* (ICD) în lume (este implicat în 15-25% din totalitatea cazurilor de diaree asociată antibioterapiei) atrage după sine o rată semnificativă a mortalităţii, aceasta fiind datorată exacerbării virulenţei tulpinilor de *C.difficile* şi creşterii vulnerabilităţii gazdei.

Căile de transmitere ale bacteriei patogene pot fi foarte complexe şi pot fi luate în discuţie: transmiterea directă de la om a om, contactul cu mediul înconjurător, contactul cu animale, transmiterea aerogenă, prin vectori şi ingestia de alimente şi apă. Deşi *C. difficile* a fost izolat din diferite tipuri de carne (6-11% în carnea de vită din magazine în Canada) nu au fost studii care să documenteze ca factor de risc pentru infecţia cu *C. difficile* consumul unui anumit produs alimentar (1, 2).

Epidemiologie. Infecţia cu *C. difficile* s-a schimbat în ultimii ani, astfel: incidenţa

bolii a crescut (de 8 ori în Quebec şi de 4 ori în Germania), afecţiunea este mai severă (rate mai mari de şoc septic, peforaţie şi colectomie - până la 18%), ICD este mai refractară la terapia standard (eşec clinic cu metronidazol de 25% în 2004 faţă de 9% în 2002) şi rate de recurenţă care s-au dublat la persoanele peste 65 ani, emergenţa şi răspândirea unor noi clone (ribotipul 027 şi 078 producătoare de toxină binară). Ribotipul PCR 078 este un exemplu de tip emergent de *C. difficile* cu transmitere de la animale la oameni şi cu o virulenţă crescută la om, dar, a cărui prevalenţă variază de la ţară la ţară (1, 2, 3).

Etiopatogenie. Dezvoltarea infecţiei cu *C.difficile* are la bază prezenţa a trei factori: vîrsta avansată sau prezenţa unor comorbidităţi, perturbarea microbiotei intestinale ca urmare a terapiei cu antibiotice sau cu agenţi antitumorali şi expunerea la forme vegetative sau spori de *C.difficile* (4).

Terapia cu antibiotice joacă un rol principal în patogeneza infecţiei cu *Clostridium difficile* prin dezechilibrul creat la nivelul microbiotei colonului. Antibioticele se caracterizează prin capacităţi diferite de a inhiba *C.difficile* şi de a stimula producerea toxinei. Cele care nu au o activitate semnificativă asupra *C. difficile* dar care au o capacitate mare de a perturba microflora intestinală (ex. ceftriaxona) favorizează apariţia ICD atît în perioada de terapie cît şi în perioada de recuperare a microflorei. De asemenea, rezistenţa la antibiotice a *C. difficile* are un rol important în epidemiologia ICD. Tulpinile rezistente la clindamicină, la fel ca şi în cazul celor rezistente la fluoroquinolone sau cefalosporine rezistă într-un mediu în care celelate microorganisme au fost suprimate pe parcursul terapiei, ducînd la apariţia infecţiei digestive. Capacitatea de a induce producerea de toxină este mai mică în prezenţa unor antibiotice ca piperacilină-tazobactam şi tigeciclină faţă de cefotaximă (5).

Cel mai adesea sunt implicate în producerea diareei cu *C. difficile*: clindamicina, penicilinele, cefalosporinele şi fluoroquinolonele. Clindamicina afectează pe termen lung flora intestinală, ceea ce creşte fereastra de susceptibilitate pentru ICD. În ultima perioadă cefalosporinele se poziţionează pe primul loc între antibioticele capabile să favorizeze ICD. (5).

Manifestări clinice. Infecţia cu *C. difficile* poate îmbrăca următoarele forme de manifestare: (1) diaree, (2) ileus (3) megacolon toxic. La pacienţii cu vârsta ≥ 65 ani, având comorbidităţi semnificative şi la cei din terapie intensivă se consideră ICD ca fiind severă chiar în absenţa semnelor care definesc colita severă (6). Deşi afectează cu predilecţie colonul, în ultima perioadă au fost comunicate un număr crescut de cazuri cu afectare ileală, multe dintre ele cu evoluţie fatală (7).

Pentru stratificarea gradului de severitate se iau în calcul următoarele caracteristici ale pacientului: vârsta > 60 ani, temperatura>38,3°C, albuminemia < 2,5 mg/dl, leucocite> 15.000/mmc, colită pseudomembranoasă, internarea în secţii de TI şi se acordă cîte 1 punct pentru primele 4 caracteristici şi cîte 2 puncte ultimelor două. Se consideră formă severă de boală dacă punctajul acumulat este ≥ 2 (8).

Diagnostic de laborator. Testarea ICD trebuie realizată la toate persoanele cu suspiciunea de diaree infecţioasă la care testele pentru enteropatogenii obişnuiţi sunt negative şi la toţi pacienţii cu diaree care au avut o spitalizare prealabilă de cel puţin 72 ore (9).

Testele de diagnostic pentru infecţia cu *C. difficile* se clasifică în teste pentru (1)

produşi ai *C. difficile* (glutamat – dehidrogenaza (GDH), acizi graşi aromaţi, toxina A şi/sauB), (2) metode de cultură pentru detecţia *C. difficile* producătoare de toxină (cultura toxigenică), şi (3) teste pentru determinarea genelor *C. difficile*. Testele de citotoxicitate în cultură celulară (CCA) şi cultura toxigenică sunt considerate ca metode standard de referinţă pentru detecţia *C. difficile.* Recent, aceste metode consumatoare de timp, care necesită o utilare specifică a laboratorului au fost înlocuite prin teste imunoenzimatice (EIA), rapide şi uşor de realizat: EIA de detectare a GDH, EIA de detectare doar a toxinei A, şi EIA de detectare a ambelor toxine A şi B (9).

Tratament. Măsurile generale în cazul ICD sunt: întreruperea antibioticelor, măsuri suportive, evitarea agenţilor antiperistaltici, măsuri de izolare pentru prevenirea transmiterii enterale.

Metronidazolul şi vancomicina au fost principalele opţiuni terapeutice încă de la sfîrşitul anilor 70, cînd a fost recunoscut rolul *C. difficile* în patogenia infecţiei digestive. Metronidazolul este medicaţia de primă-intenţie pentru *terapia unui episod iniţial* de ICD formă uşoară-moderată (500mg x3/zi x10-14 zile) (9, 10).

În scopul limitării emergenţei enterococilor şi stafilococilor rezistenţi la vancomicină şi al diminuării costurilor, utilizarea vancomicinei în spitale este limitată doar la cazurile care nu răspund la metronidazol sau la pacienţii cu forme severe de ICD sau cu multiple recurenţe (125 mg/zi po x 10-14 zile).

În cazul *formelor severe*, complicate de ICD se poate administra vancomicina oral (intrarectal dacă există ileus)(doză de 500 mg po şi 500 mg în 100 ml ser fiziologic intrarectal/zi) asociată sau nu cu metronidazolul (500mg x3/zi).

În terapia unui *episod iniţial sau a unei prime recurenţe* a ICD, în situaţia în care nu se poate administra terapia orală se recomandă metronidazol 500 mg i.v. x3/zi timp de 10 zile atît în formele severe cît şi în celelalte non-severe, asociat cu vancomicină intracolonic 500 mg în 100 ml ser fiziologic la fiecare 4-12 ore şi/sau vancomicină 500 mg - o priză/zi pe sondă nasogastrică (6).

Recurenţele ICD survin cel mai adesea la 7-14 zile după întreruperea terapiei sugerînd mai curînd o recădere decît o reinfecţie. Recăderea se înregistrează la 15-35% din pacienţii care au avut doar 1 episod anterior şi la 33-65% din cei care au prezentat ≥ 2 episoade anterioare acestea datorîndu-se unei continue expuneri la patogen (fie prin reinfectare din mediul înconjurător, fie recădere de la o sursă endogenă) (11)

Nu se indică metronidazol pentru un episod ulterior primei recurenţe a ICD sau pentru terapia pe termen lung datorită potenţialului de neurotoxicitate cumulativă (10).

Procentul de recăderi după tratamentul cu oricare din cele două antibiotice de elecţie este similar (14-15%) (8).

Tratamentul celei de-a doua recurenţe şi ale celor ulterioare se realizează cu vancomicină 125 mg po timp de cel puţin 10 zile. Poate fi luată în considerare strategia de tip o doză de 125 mg la fiecare 3 zile timp de 3 săptămîni.

Dacă terapia orală nu poate fi administrată pentru tratamentul ICD la > a doua recurenţă se recomandă metronidazol 500 mg x3 i.v./zi timp de 10 -14 zile plus cu vancomicină intracolonic (retenţionată intrarectal) 500 mg în 100 ml ser fiziologic la fiecare 4-12 ore şi/sau vancomicină 500 mg-o priză/zi pe sondă nasogastrică. Vancomicina ar putea fi înlocuită cu teicoplanin 100 mg x 2/zi în toate cazurile

mai sus menţionate (6).

În prezent rezistenţa la metronidazol a *C. difficile* ajunge la 6%, fiind o rezistenţă de tip heterogen. Testarea sensibilităţii la antibiotice s-ar impune deoarece asistăm la o creştere a circulaţiei tulpinilor cu CMI a metronidazol de peste 2mg/l, şi ar permite detectarea tulpinilor cu heterorezistenţă şi cu rezistenţă la rifaximin, în condiţiile în care ne confruntăm cu o rată mare de eşec la terapia cu metronidazol. Efectuarea antibiogramei se recomandă în următoarele situaţii: dacă este o formă severă de boală şi se are în vedere o altă terapie decât vancomicina, dacă evoluţia clinică nu este favorabilă în cursul terapiei, în caz de izbucnire epidemică, dacă este un episod de recurenţă şi pentru monitorizarea anuală a trendului de rezistenţă la antibiotice într-un spital sau o anumită regiune (12).

Dacă simptomele se agravează sau nu se ameliorează după 3-4 zile de tratament se consideră eşec terapeutic, situaţie în care se recomandă switch-ul cu vancomicină 125-250 mg p.o la fiecare 6 ore (dacă pacientul primea metronidazol) şi se solicită consult chirurgical în vederea unei eventuale colectomii.

Noi strategii terapeutice. Dat fiind eficienţa limitată a terapiilor actuale pentru ICD sunt în curs de derulare un număr impresionant de studii care evaluează eficienţa unor noi agenţi terapeutici.

Fidaxomicina este primul reprezentant al antibioticelor macrociclice orale, cu acţiune bactericidă importantă împotriva *C. difficile*, lipsită de rezistenţă încrucişată cu alte antibiotice. Spectrul său de activitate asupra florei intestinale normale este limitat (fiind inactiv pe *Candida*, bacterii Gram-negative, numeroşi Gram-pozitiv şi anaerobi); atacă doar bacteriile patogenice şi protejează flora gastro-intestinală normală, spre deosebire de vancomicină şi metronidazol care suprimă creşterea florei endogene normale (13)

În studiul comparativ fidaxomicină versus vancomicină, Louie şi col înregistrează rezultate similare privind rata de vindecare clinică în cele două loturi, beneficiul maxim al fidaxomicinei fiind la cei cu recurenţe (15% vs 25%) (14).

Tigeciclina prezintă activitate inhbitorie împotriva *C. difficile* în colonul şoarecilor de laborator şi nu permite producerea de toxină (15).

Într-un studiu multicentric, randomizat, dublu-orb, placebo-controlat, recent publicat de Lowy şi colaboratorii a fost evaluată eficienţa a doi anticorpi monoclonali neutralizanţi cu acţiune împotriva toxinei A şi B administraţi concomitent cu antibioterapia standard. Rezultatele obţinute relevă o reducere semnificativă a ratei recurenţelor la pacienţii care au primit anticorpi faţă de placebo (8% *vs* 32%) (16).

Imunoglobulinele cu administrare intravenoasă s-au dovedit a fi urmate de un răspuns clinic favorabil la un subgrup de pacienţi cu numeroase recurenţe ale ICD. Doza poate fi de 300 mg/kg sau aceeaşi doză în 5 perfuzii zilnice (17).

Administarea de materii fecale colectate de la persoane sănătoase, prin colonoscopie, la nivelul tuturor segmentelor colonului, sau infuzia pe tub nasogastric au dat cele mai bune rezultate în tratamentul recurenţelor (11).

Eficienţa probioticelor (*Lactobacilus GG, Saccharomyces boulardii*) în profilaxia şi tratamentul infecţiei cu *C. difficile* nu este încă dovedită. Aceste produse nu se recomandă la pacienţii cu risc pentru translocarea bacteriană şi nici la pacienţii cu catetere venoase centrale (18).

Preparatele care conţin *Lactobacillus*

casei imunitass par să prevină ICD, fapt susţinut de un studiu prospectiv în care nu a apărut nici un episod de ICD la cei care au primit antibiotice şi *Lactobacillus* faţă de 17% episoade la lotul fără *Lactobacillus* (19).

Este posibil ca o strategie viitoare să se baze pe asocierea dintre un antibiotic şi o terapie imunologică.

CONCLUZII

Noile abordări de întrerupere a ciclului infecţiei cu *C. difficile*, concomitent cu acordarea unei atenţii speciale administrării unei antibioterapii adecvate şi cu punerea în practică a măsurilor de prevenţie şi control ar putea duce la limitarea substanţială a aceastei infecţii cu o prevalenţă în creştere şi greu de manageriat.

NOUTĂȚI

PROGRESIA TULBURĂRILOR DE SOMN ŞI INCIDENŢA BOLILOR CARDOIVASCULARE

Tulburările respiratorii prezente în cursul apneei de somn sunt generatoare de complicaţii cardiovasculare. Sleep Heart Health Study a înrolat 2721 pacienţi (vârsta medie 62 de ani, 57% femei), fără boală cardiovasculară la intrarea în studiu, care au fost supuşi la 2 polisomnografii la interval de 5 ani. S-a consemnat incidenţa bolilor cardiovasculare, incluzând infarctul de miocard, insuficienţa cardiacă sau stroke. Pacienţii la care s-a evidenţiat o rată crescută a evenimentelor cardiovasculare au avut cei mai crescuţi indici de apnee obstructivă şi centrală. Diferenţa dintre indexul apnee-hipopnee la pacienţii cu şi fără complicaţii cardiovasculare a fost de 2,75 evenimente/oră (interval de încredere 95%, 0,1 versus 1,75, p=0,04). Studiul evidenţiază relaţia reciprocă care există între tulburările de respiraţie din timpul somnului şi complicaţiile cardiovasculare, persistenţa unor afecţiuni cardiovasculare pe o perioadă de peste 5 ani, determinând apariţia unor tulburări respiratorii nocturne. PREVALENCE OF CHRONIC HEPATITIS B VIRUS (HBV) INFECTION IN CLOSED COMMUNITIES AND RISK BEHAVIOUR (Abstract): **Aim:** To determine the prevalence of chronic hepatitis B virus infection in closed communities and the relations between the risk behavior and VHB infection. **Material and methods:** In this study we included persons deprived of personal freedom at Bacau Correctional Facility. The subjects filled out a questionnaire, which contained identification and epidemiologic data (detention history, evaluation of the risk factors), as well as an informed consent. All subjects were tested for HBsAg. **Results:** According to the performed tests, the general prevalence of hepatitis B and C in this correctional facility was 15,34%, with a prevalence of hepatitis B of 10,74%. Although these figures show a higher prevalence in this population than within the general population, they are lower than the figures reported in correctional facilities from other countries. **Conclusions**: The results confirm the fact that the population in correctional facilities is at high risk for hepatitis B infection, the ways of disease transmission being already known (infected blood, injected drugs, tattooing, homosexual relationships). **Key words:** HEPATITIS B VIRUS, PREVALENCE OF HBV INFECTION, RISK BEHAVIOR, CORRECTIONAL FACILITIES

În ciuda existenței unor metode eficiente de prevenire a infecției cu VHB, aceasta continuă să reprezinte o importantă problemă de sănătate publică pe plan mondial. Peste 65% din populația lumii trăieşte în zone cu prevalență crescută a infecției cu VHB (1), aceasta reprezentând a IX-a cauză de deces pe glob şi prima cauză de mortalitate prin carcinom hepatocelular (CHC) în țări din Asia de Sud-Est şi Africa Subsahariană (2). Conform datelor OMS (3), dar şi a unor studii (4), estimarea prevalenței infecției VHB în populația generală indică existența a 350-400 milioane de persoane cu infecție persistentă. Decesele cauzate de afectarea acută sau cronică determinate de VHB se ridică la 600.000 – 1 milion pe an (3,4). În fiecare an, la nivel mondial, sunt afectate între 10 şi 30 milioane de persoane, multe dintre ele fiind copii şi tineri (5).

Literatura de specialitate atestă existența unor grupuri populaționale cu risc crescut de infecție (4,6). În rândul lor se pot deosebi mai multe subgrupuri: utilizatorii de droguri intravenoase, partenerii sexuali

ai purtătorilor cronici de VHB, persoane cu parteneri sexuali multipli, inclusiv homosexuali, heterosexuali cu istoric de BTS - boli cu transmitere sexuală, deținuții - în funcție de numărul de condamnări, de anii petrecuți în instituții corecționale). Acestora li se adaugă şi personalul care deserveşte penitenciarele (mai ales cei care au un contact prelungit şi strâns cu deținuții - personal sanitar, supraveghetori).

Legat de persoanele private de libertate, OMS şi-a exprimat temerea că sistemul penitenciar (care la nivel mondial deserveşte aproximativ 9 milioane deținuți pe an) reprezintă un rezervor de menținere şi amplificare a transmiterii infecției în comunitate după liberarea deținuților (3). Trebuie menționat că 85% din persoanele intrate în penitenciar sunt asociate cu un comportament la risc preîncarcerar, comportament pe care îl continuă în penitenciar şi îl transmite şi celor neiniției (7). De aceea, multe țări propun ca penitenciarele să fie ținta majoră a programelor de prevenție primară, secundară şi terțiară (7,8).

Prevalența acestor boli în penitenciar este mare, comportamentul la risc este un fapt comun, programele de prevenție sunt rare (8-11) sau inexistente, iar dinamica (turnoverul) efectivelor în/şi din astfel de instituții este crescută. La aceasta se adaugă agregarea importantă a unor grupuri provenite din comunități având crescut comportamentul la risc, dar care au un nivel socioeconomic şi educațional scăzut (9).

Scopul acestui studiu a fost stabilirea prevalenței infecției virale B în colectivități închise la persoanele cu comportament la risc, iar scopul secundar a fost stabilirea de corelatii dintre diferiți parametri caracteristici (perioada de detenție, numărul de condamnări, consumul de droguri cu administrare intravenoasă, numărul partenerilor sexuali, orientarea sexuală) şi rata infecției virale hepatice B.

MATERIAL ŞI METODĂ

În studiu au fost incluşi rezidenții Penitenciarului Bacău pe o perioadă de 3 ani (2007-2010). După semnarea consimțământului informat, subiecții au completat un chestionar epidemiologic şi au fost supuşi unui examen clinic general. Chestionarul epidemiologic a cuprins date de identificare şi date epidemiologice (istoricul detenției/detențiilor, evaluarea factorilor de risc: administrare de droguri injectabile, tatuare, hetero/autoagresiuni, partajul obiectelor de toaletă, intervenții chirurgicale sau stomatologice, călătoria în străinătate şi eventual în zone cu endemicitate crescută). Toți subiecții au fost testați pentru prezența Ag HBs prin metoda ELISA.

Datele statistice au fost prelucrate cu ajutorul programului *SPSS 16.0*. Am utilizat pentru compararea valorilor testul Chi pătrat, iar valorile neparametrice au fost interpretate cu ajutorul testului Mann-Whitney de comparare a rangurilor.

REZULTATE

Din totalul de 500 deținuți din Penitenciarul Bacău, 326 au semnat consimțământul informat şi doar 141 au completat chestionarul epidemiologic.

Vârsta medie a lotului a fost 30,94 ± 9,67 ani (femei: 32,84 ± 8,92 ani, bărbați: 30,65 ± 9,77 ani). Pentru a vedea dacă s-au înregistrat diferențe semnificative statistic între valorile vârstei pe diferitele categorii de subiecți incluşi în lotul de studiu, am folosit testele de semnificație statistică. Testul de normalitate Kolmogorov - Smirnov a aratat că valorile vârstei nu respectă legea de distribuție normală ($Z = 1.805$, $p = 0.003$, SS), deci pentru a compara aceste

valori am folosit doar teste neparametrice. Am folosit testul Mann-Whitney de comparare a rangurilor, care a aratat că nu există diferențe semnificative statistic între valorile vârstei pe sexe (U = 5200.500, p = 0.084, NS), şi nici între subiecții pozitivi/negativi pentru Ag HBs (U = 4068.500, p = 0.052, NS), respectiv pentru anticorpi anti VHC (U = 2172.000, p = 0.229, NS). Ponderile pe sexe ale persoanelor identificate pozitiv nu au diferit semnificativ statistic în nici unul dintre cazuri (p=0,367).

A fost completat un număr de 141 chestionare, adică 43,25% dintre subiecții incluşi în studiu au acceptat să răspundă la această formă de interviu. La 197 (60,43%) dintre deținuții incluşi în studiu s-au efectuat analize medicale complete. Au existat 31 de persoane (22,0%) pentru care au fost realizate analizele medicale complete şi care au acceptat să completeze şi chestionarul, neexistând situații de p.p.l incluse în studiu şi care să nu fi răspuns măcar la una dintre cele două forme de investigare folosite. Întregul lot a fost însă testat pentru prezența Ag HBs.

În urma analizelor efectuate s-a obținut o prevalență a Ag HBs în lot de 10,74%. Majoritatea celor incluşi în studiu au făcut parte din grupa de vârstă 20-45 ani, prezența Ag HBs fiind preponderentă la aceeaşi grupă de vârstă.

Pentru ambele sexe mediul de proveniență a fost preponderent cel urban. Proporția pacienților cu infecție virală B din mediul urban a fost de 68% față de mediul rural unde s-a înregistrat o proporție de 32% (OR 1,61, p=0,344).

Cei mai mulți subiecți cu infecție virală B au fost: de etnie română (92%), aveau terminate 12 clase (liceul) ca nivel de studii 70,2%, nivelul socio-economic era mediu spre scăzut (60,9%, p=0,32), aveau statusul marital incert (divorțat, văduv sau necăsătorit) (30,5%), fiind recidiviști sau având condamnări cu o durată de cel puțin 2 ani.

În acest studiu s-au luat în calcul mai mulți factori de risc pentru transmiterea infecției virale B (tab. I).

TABELUL I

Factori de risc corelați cu VHB la pacienții din comunități închise

Factori de risc	OR	p
Istoric familial de VHB	14,157	<0,001
Locuit în străinătate >1 lună	0,974	0,038
Tatuaje	2,850	0,023
Boli cu transmitere sexuală	2,061	0,173
Homosexualitate	16,132	<0,001
Leziuni autoprovocate	1,211	0,714
Utilizare de droguri intravenoase	2,705	0,026

Tatuajele au fost realizate în mare proporție (82,3%) în penitenciar (de cele mai multe ori de colegii de cameră) şi doar 8,9% au apelat la saloane specializate (înainte de intrarea în penitenciar). Cu toate acestea, Ag HBs a fost detectat la 36,9% din cei care şi-au realizat tatuajul în penitenciar. Dintre pacienții cu VHB 16,6% au recunoscut că utilizau obiecte de toaletă comune (OR 2,04, p=0,132).

DISCUȚII

Infecția cu VHB recunoaşte drept căi majore de transmitere calea sanguină şi cea sexuală; calea de transmitere verticală (materno-fetală) nu a făcut obiectul studiului nostru.

Prevalența infecției cronice virale B în Penitenciarul Bacău a fost de 10,74% la grupa de vârstă 20-45 ani. Această prevalență este crescută față de prevalența de 5,05% identificată în studiile anterioare

(12) la aceiaşi grupă de vârstă, însă în populaţia generală a României, ceea ce relevă riscul crescut pe care îl au subiecţii aflaţi în colectivităţi închise.

Structura populaţiei penitenciare a influenţat unele rezultate. Faptul că în perioada desfăşurării studiului populaţia de sex feminin a Penitenciarului Bacău era de aproximativ 5% din total a determinat o prevalenţă mai mare a infecţiei VHB în rândul persoanelor de sex masculin. Aceste rezultate sunt în concordanţă cu cele obţinute într-un studiu (12) efectuat la nivel naţional, în care probabilitatea infecţiei cronice cu VHB era de 1,55 ori mai mare la bărbaţi ca la femei. Spre deosebire de acest studiu însă, mediul de proveniență (urban sau rural) are un rol opus. Dacă în studiul citat mai sus probabilitatea de a fi infectat cronic cu VHB era de 1,32 ori mai mare în mediul rural (fapt explicat prin standardul scăzut socio-economic, sanitar şi educaţional, cultura specifică şi practicile tradiţionale), în studiul nostru datele arată că există de 0,693 ori mai puţine şanse ca o persoană din mediul rural să fie pozitivă pentru VHB decât o persoană din mediul urban. Explicaţia este simplă: la nivel penitenciar, grupurile cu risc provin în special din mediul urban, aici aceste grupuri fiind în număr mai mare, având mai mulţi membri, care se angajează mai frecvent în activităţi comportamentale cu risc crescut pentru infecţie. Un alt factor protector este reprezentat de nivelul de studii – subiecţii cu studii universitare au şanse (risc) mai mici de a dezvolta infecţia cu VHB decât cei al căror nivel de pregătire se opreşte la şcoala primară, gimnaziu sau liceu. Deoarece etnia majoritară a fost cea română, a rezultat un număr mai mare de persoane de etnie română cu VHB prezent, decât de etnie rromă (23 versus 2), ducându-ne la concluzia că la populaţia română avem de 1,191 ori mai multe şanse de identificare a Ag HBs decât la rromi – un risc slab-moderat. Trebuie luată în considerare însă şi acurateţea cu care cei care au completat chestionarul şi-au declarat etnia. Statusul marital este un aspect important – grupul celor necăsătoriţi şi divorţaţi era de aproape două ori mai numeros decât al celor căsătoriţi în ceea ce priveşte prezenţa Ag HBs.

Un comportament la risc, frecvent întâlnit printre deţinuţi, este tatuarea. Relaţia dintre comportamentul la risc al deţinuţilor şi transmiterea virusurilor hepatice în rândul acestora este bine stabilită în literatura de specialitate (13-15). Tatuajele nu reprezintă un factor de risc pentru transmiterea VHB. Un alt comportament la risc este reprezentat de relaţiile sexuale cu parteneri de acelaşi sex (homosexualitatea). Acestea determină un risc pronunţat (de 3,897 ori mai multe şanse) pentru infecţia cu VHC. Numărul de condamnări şi anii petrecuţi în detenţie duc la un risc, deşi slab, de a achiziţiona infecţia cu virusurile hepatice. Aceste argumente sunt în favoarea aserţiunii potrivit căreia detenţia, în general, prin modul de viaţă şi comportamentul pe perioada executării pedepsei are un rol important în transmiterea infecţiei cu virusuri hepatice şi în perpetuarea unui important rezervor de virus, care ulterior (la eliberare) se va întoarce în comunitate. Rezultatele sunt contrare studiului citat mai înainte (12) potrivit căruia detenţia nu se corelează din punct de vedere epidemiologic cu infecţia VHB.

Alt comportament la risc este reprezentat de leziunile autoprovocate în perioada detenţiei. Ele au un risc slab pentru infecţia VHB şi se corelează cu numărul de condamnări şi anii de detenţie.

În studiul efectuat nu am găsit ca fiind

factor de risc pentru infecția cu VHB administrarea de tratamente injectabile la domiciliu, împărțirea obiectelor personale de igienă, accidentele de circulație, acupunctura, frecventarea saloanelor de cosmetică/manichiură/pedichiură, intervențiile chirurgicale sau spitalizările.

Un fapt demn de semnalat, recunoscut de întreaga literatură de specialitate (16-19), este faptul că vaccinarea pentru VHB elimină complet riscul de a mai contracta această boală.

Este posibil ca realizarea unui astfel de studiu în facilități corecționale cu o altă structură a populației să conducă la date mai apropiate de cele din alte țări. Totuşi datele obținute susțin necesitatea imperioasă a elaborării unor programe de screening, prevenție şi tratament în rândul persoanelor instituționalizate, dar şi întreprinderea unor inițiative legislative care să sprijine astfel de programe.

CONCLUZII

Datele obținute demonstrează că infecția virală B este mai frecventă în colectivitățile închise decât în populația generală, în concordanță cu creşterea expunerii la factorii de risc. Factorii de risc se suprapun cu cei ai populației generale, cu o frecvență crescută a utilizării de droguri intravenoase, a tatuajelor şi a comportamentului bi/homosexual.

NOUTĂȚI

VALOAREA PREDICTIVĂ A INDICILLOR ANTROPOMETRICI PENTRU MORTALITATEA ŞI MORBIDITATEA PACIENȚILOR DIALIZAȚI

Evaluarea *status*-ului nutriţional al pacienţilor dializaţi este importantă deoarece malnutriţia protein calorică este un factor care influenţează morbiditatea şi mortalitatea acestora. Scopul acestui studiu a fost să argumenteze valoarea predictivă a parametrilor antrpopometrici şi modalitatea în care aceste două caracteristici se corelează. Studiul a inclus 242 pacienţi. Măsurătorile antropometrice au fost făcute în timpul iernii şi s-au referit la date privind pliul cutanat, circumferinţa braţului, înălţime şi greutate. Procentul de grăsime corporală a fost calculat în funcţie de pliul cutanat prezent în regiunea tricepsului, bicepsului, suprascapulară şi suprailiacă. Indicele de masă corporală (BMI) rata catabolizării proteinelor şi factorii de risc cardio-vasculari au fost de asemenea valori luate în discuţie. În urma analizei datelor au fost găsite corelaţii semnificative între parametrii antopometrici (analiza statistică folosită fiind regresia Cox extinsă). De asemenea, fiecare parametru investigat s-a corelat independent cu mortalitatea şi morbiditatea pacienţilor investigaţi. Parametrul cu valoarea predictivă cea mai mare a fost circumferinţa braţului, indicele de masă corporală fiind considerat doar un factor de risc. (Stosovic M, Stanojevic M, Ogrizovic S, Jovanovic, The predictive value of anthropometric parameters on mortality in haemodialysis patients. *NephrolDial Transplant.* 2011; 26: 1367-1374).

MALADIA PEPTICĂ ÎN CIROZA HEPATICĂ: ROLUL INFECŢIEI CU *HELICOBACTER PYLORI* ŞI CONDUITA TERAPEUTICĂ

Dana Mitrică, R. Constantinescu, V.L. Drug, C. Stanciu
Universitatea de Medicină şi Farmacie „Gr. T. Popa" Iaşi
Facultatea de Medicină
Institutul de Gastroenterologie şi Hepatologie Iaşi

PEPTIC ULCER DISEASE IN LIVER CIRRHOSIS: ROLE OF *HELICOBACTER PYLORI* INFECTION AND THERAPEUTICAL APPROACH (Abstract): Peptic ulcer has frequently been associated with liver cirrhosis. The death rate for peptic ulcer in cirrhotics has been reported to be five times higher than in general population. The underlying mechanisms are poorly understood. Different factors have been claimed to be involved, such as alterations in serum gastrin level, gastric acid secretions, mucosal blood flow and decreased prostaglandin production in gastric mucosa. Moreover, *Helicobacter pylori* infection, when accurately assessed, is detectable in most peptic ulcer cirrhotics. Since the *H. pylori* infection strongly correlates with peptic ulcer in general population, it is necessary to clarify the role of *H. pylori* in the pathogenesis of peptic ulcer in cirrhosis before eradication can be proposed as a preventive measure. **Key words**: PEPTIC ULCER DISEASE, LIVER CIRRHOSIS, HELICOBACTER PYLORI

Se estimează că infecţia cu *Helicobacter pylori* (*H. pylori*) reprezintă cea mai frecventă infecţie întâlnită la om, peste 50% din populaţia globului şi peste 60% din populaţia României fiind infectată cu *H. pylori*. Este unanim recunoscută implicarea sa în producerea gastritei cronice, ulcerului gastric şi duodenal, neoplasmului gastric şi limfomului gastric MALT, dar locul său în tabloul clinico-evolutiv al cirozei hepatice rămâne un subiect controversat (1).

Astfel, relaţia dintre infecţia cu *H. pylori*, generatoare de patologie ulceroasă gastroduodenală şi ciroza hepatică – boală cronică invalidantă – devine o problematică medicală importantă şi o provocare pentru sistemul sanitar, incomplet elucidată la ora actuală.

INFECŢIA CU *H. PYLORI* ÎN CIROZA HEPATICĂ

Literatura de specialitate a fost invadată de semnale frecvente privind rolul bacteriei descoperite în 1983 de către Warren şi Marshall în patogeneza bolilor extragastrice, în prezent *H. pylori* fiind obiect de cercetare pentru aproape toate specialităţile medicale. Întrebarea care încă îşi aşteaptă răspunsul este în ce măsură un microorganism cu localizare exclusiv gastrică intervine în mecanismele patogenice ale unor maladii extragastrice (2).

H. pylori interferă atât cu mijloacele de apărare ale stomacului (cantitatea şi calitatea mucusului, secreţia de bicarbonat), cât şi cu cele de agresiune (secreţia de gastrină, HCl, pepsină). *H. pylori* este implicat în etiologia ambelor localizări ale bolii ulceroase (duodenal şi gastric), proporţia celor infectaţi fiind mai ridicată în primul caz. S-a demonstrat că *H. pylori* determină tulburări în secreţia hormonilor polipeptidici gastrointestinali la nivelul antrului gastric, cu rol determinant în ulcerogeneză. Se admite în prezent că *H. pylori* are un efect hipergastrinemiant, corelat pozitiv cu creşterea secreţiei acide şi peptice, atât la subiecţii cu ulcer, cât şi la cei fără boală ulceroasă (3).

Ulcerul *H. pylori* pozitiv este frecvent întâlnit într-o serie de afecţiuni : boli hepato-biliare (ciroza hepatică, litiaza biliară, hepatocarcinom), boli cardio-vasculare (cardiopatia ischemică, ateroscleroza cerebrală), boli autoimune (tiroidita autoimună), boli cutanate alergice (urticaria cronică idiopatică), boli hematologice (anemia sideropenică), boli neurologice (boala Parkinson), boli metabolice (diabetul zaharat), boli respiratorii (bronşita cronică, astmul bronşic). În majoritatea bolilor studiate, prevalenţa infecţiei cu *H. pylori* este mai ridicată decât la populaţia de control. Rămâne de stabilit rolul patogen al bacteriei şi dacă localizarea sa în alte organe este primară sau secundară suferinţelor respective (2).

Deşi infecţia cu *H. pylori* este frecvent asociată cirozei hepatice, rolul său patogenetic prin mecanisme în mare parte de tip imun este încă un subiect controversat şi incomplet elucidat (3, 4).

Prevalenţa infecţiei cu *H. pylori* la pacienţii cirotici este raportată în limite foarte largi, diferenţele datorându-se atât mijloacelor diferite de diagnostic utilizate, precum şi posibil criteriilor de selecţie a bolnavilor.

Astfel, 14 studii recente înrolând, un număr de 1499 de bolnavi diagnosticaţi cu ciroză hepatică, au observat o seroprevalenţă medie de 70,2%, situându-se între 43,5% şi 93,9% (3, 5, 6).

Utilizând metode invazive de diagnostic (examen histologic, testul rapid la urează, tehnici de cultură), prevalenţa infecţiei cu *H. pylori* în ciroza hepatică a înregistrat o reducere notabilă, fiind în medie de 46,1%, după cum reiese din 21 de studii care au inclus 1331 de bolnavi (3).

Un studiu recent efectuat pe 186 de cirotici demonstrează că prevalenţa infecţiei cu *H. pylori* evaluată prin teste serologice a fost semnificativ mai ridicată faţă de examenul histologic (66% vs. 44%). Sensibilitatea testului serologic la bolnavul cu ciroză hepatică este de 85,4%, iar specificitatea de 38,4%, net redusă faţă de lotul de control (7). Acest fenomen se poate explica prin reducerea imunocompetenţei, precum şi prin reacţia încrucişată dintre anticorpii anti-*H. pylori* şi antigenele organismului gazdă. Alţi autori au observat o prevalenţă similară a infecţiei cu *H. pylori* la bolnavii cirotici cu cea a lotului de subiecţi sănătoşi (8).

Cercetările din ultimii ani au adus în discuţie posibile corelaţii între prevalenţa infecţiei cu *H. pylori* şi profilul etiologic al suferinţelor hepatice. Astfel, există studii care arată o proporţie ridicată de bolnavi cu ciroză hepatică alcoolică infectaţi cu *H. pylori* comparativ cu etiologia post virală (9), sunt autori care notează preponderent etiologia virală în asociere cu infecţia cu *H. pylori* (8, 10) şi, în sfârşit sunt date care nu afirmă nici o asociere semnificativă în acest sens (11).

Referitor la corelaţia dintre severitatea cirozei hepatice evaluată prin scorul Child-Pugh şi infecţia cu *H. pylori*, se nasc de asemenea controverse. Majoritatea autorilor concluzionează că insuficienţa hepatică nu influenţează prevalenţa infecţiei cu *H. pylori* (5, 6). Totuşi, un studiu recent remarcă o corelaţie invers proporţională între severitatea suferinţei hepatice şi prevalenţa infecţiei cu *H. pylori* (8). Se pare că *H. pylori*, bacterie cu un echipament enzimatic foarte bogat care îi conferă o rezistenţă deosebită, nu reuşeşte să supravieţuiască în mediul gastric ostil al bolnavului cirotic.

ULCERUL PEPTIC

Ulcerul gastro-duodenal, una dintre cele mai comune suferinţe ale tubului digestiv recunoaşte o patogeneză multifactorială. În mod convenţional, factorii patogenetici se clasifica în două categorii : factori de agresiune (acidul clorhidric, pepsina, antiinflamatoarele non-steroidiene, fumatul, refluxul duodeno-gastric) şi factori de apărare (secreţia de mucus şi bicarbonat, prostaglandinele, celulele epiteliului de suprafaţă, microcir-

culaţia sanguină). *H. pylori* este o verigă patogenetică ce interferă atât cu mijloacele de agresiune, cât şi cu cele de apărare.

Majoritatea datelor publicate în literatură afirmă o prevalenţă crescută a bolii ulceroase la pacienţii diagnosticaţi cu ciroză hepatică, cu o incidenţă raportată anual de 10 ori mai mare faţă de populaţia generală (5, 12).

Ulcerul peptic este responsabil de 7,4--16% din totalul hemoragiilor digestive superioare la bolnavul cirotic. Rata mortalităţii prin ulcer peptic este de circa 5 ori mai ridicată la ciroze decât în populaţia generală, la aceasta contribuind tulburările de coagulare şi trombocitopenia specifice insuficienţei hepatice (3).

Relaţia ciroză hepatică-ulcer peptic este complexă şi controversată. Mecanismele ulcerogenezei din ciroza hepatică prezintă încă numeroase lacune care urmează a fi acoperite de cercetări viitoare. Au fost incriminaţi o serie de factori precum : infecţia cu *H. pylori*, secreţia clorhidro-peptică, perturbările mucoasei gastrice din gastropatia portal-hipertensivă, consumul de antiinflamatorii non-steroidiene, etilismul cronic. În ciroza hepatică se descriu o multitudine de evenimente care se derulează la nivelul mucoasei gastro-duodenale : reducerea nivelului de prostaglandine E2, secreţie inadecvată de mucus şi bicarbonat, creşterea retrodifuziunii ionilor de hidrogen, alterarea fluxului sangvin mucosal (13).

Calvet si col. au condus un amplu studiu, concluzionând că factorii de risc majori asociaţi bolii ulceroase din ciroza hepatică sunt reprezentaţi de infecţia cu *H. pylori* şi sexul masculin (14).

Prevalenţa ulcerului *H. pylori* pozitiv în ciroza hepatică, stabilită prin metoda serologică variază între 44-95% în cazul ulcerului duodenal şi între 50-87% în localizările gastrice (5, 6). Seropozitivitatea *H. pylori* este considerată de cei mai mulţi autori ca fiind un factor de risc independent în producerea ulcerului la bolnavul cu ciroză hepatică (14).

În conformitate cu două studii recente în care s-au prelevat biopsii de la nivelului *antrum*-ului gastric, infecţia cu *H. pylori* a fost detectată la 40% din pacienţii cirotici cu ulcer peptic, respectiv la 51,2% dintre bolnavii diagnosticaţi concomitent cu ulcer duodenal şi ciroză hepatică (15, 16).

În condiţiile în care pentru diagnostic se apelează simultan la examenul histologic, cultură şi test respirator cu uree marcată, infecţia cu *H. pylori* se decelează la o proporţie mare de cazuri (94% din 19 bolnavi cirotici şi ulceroşi fiind infectaţi cu *H. pylori*) (17).

Un studiu care a evaluat 60 de bolnavi cu ciroză hepatică şi ulcer, utilizând atât examinarea histologică cât şi testul rapid la urează, cu prelevare de biopsii antrale şi corporeale a evidenţiat infecţia cu *H. pylori* la 88% din cazurile cu ulcer duodenal şi la 83% din cazurile cu ulcer gastric (18).

S-a semnalat, de asemenea că există o prevalenţă semnificativ mai ridicată a ulcerului gastric la bolnavii cirotici infectaţi cu *H. pylori* faţă de lotul de control (22% vs. 3%, $p < 0,0001$), în timp ce prevalenţa ulcerului duodenal este similară în cele două grupuri (16% vs. 19% $p = 0,5$). În acest studiu s-a observat că ulcerul peptic *H. pylori* pozitiv a fost responsabil de 12% din hemoragiile digestive superioare (18).

TRATAMENTUL INFECŢIEI CU *HELICOBACTER PYLORI* ÎN CIROZA HEPATICĂ

Având în vedere prevalenţa înaltă a ulcerului peptic în ciroza hepatică, precum şi rolul ulcerogen de necontestat pe care îl deţine infecţia cu *H. pylori*, tratamentul de eradicare al infecţiei este pe deplin justificat, fiind un factor decisiv în creşterea ratei de vindecare a ulcerului, reducerea recurenţelor şi complicaţiilor, scăderea duratei şi costurilor de spitalizare şi, în final reducerea ratei mortalităţii la aceşti bolnavi.

Există, însă şi dificultăţi în alegerea schemei de eradicare. Oricum pacienţii cirotici primesc o multitudine de medicamente (diuretice, dizaharide, β-blocante), astfel incât un tratament antibiotic adiţional este greu de acceptat de către bolnav şi privit cu rezervă de către clinician.

Pe de altă parte, insuficienţa hepatică influenţează în mare măsură farmaco-cinetica medicamentelor. În ciroza hepatică se constată o prelungire a timpului de înjumătăţire al Metronidazolului, ceea ce se asociază cu o creştere a frecvenţei reacţiilor secundare, în timp ce are loc şi o reducere a concentraţiei serice a 14-OH-claritromicinei (metabolitul activ al Claritromicinei), conducând la scăderea eficienţei terapiei. În plus, studii recente semnalează că infecţia cu *H. pylori* alterează activitatea citocromului P-450, ceea ce determină perturbarea metabolizării Omeprazolului la nivel hepatic (3).

Un studiu randomizat incluzând 83 de pacienţi cu ciroză hepatică a comparat rata eradicării infecţiei cu *H. pylori* după dublă terapie administrată timp de 2 săptămâni (Omeprazol 20 mg x 2/zi şi Amoxicilină 1000 mg x 2/zi), cu triplă terapie administrată timp de 1 săptămână (Omeprazol 20 mg x 2/zi, Claritromicină 250 mg x 2/zi şi Tetraciclină 500 mg x 2/zi). S-a obţinut o rată de eradicare similară între cele două regimuri terapeutice (87,8% vs. 85,7%) (19).

Eficienţa dublei asocieri în eradicarea infecţiei cu *H. pylori* a fost constatată şi în alte studii, obţinându-se eradicarea în 21 de cazuri din 26 trataţi (81%), respectiv în 91% din 11 pacienţi cirotici trataţi (20).

Alţi autori au verificat regimurile terapeutice sub forma triplei terapii: rata eradicării a fost de 86% din 22 de pacienţi trataţi cu Omeprazol 20 mg x 2/zi, Claritromicină 500 mg x 2/zi şi Amoxicilină 1000 mg x 2/zi timp de 1 săptămână (21), respectiv de 88% din 27 de pacienţi trataţi utilizând aceeaşi schemă timp de 10 zile (22).

Un studiu recent a evaluat eficienţa triplei terapii (inhibitor de pompă de protoni, Amoxicilină 1000 mg x 2/zi şi Claritromicină 500 mg x 2/zi) la două loturi de bolnavi cu *H. pylori* pozitivi: 59 diagnosticaţi cu hepatită cronică şi 104 cu ciroză hepatică. Rata eradicării a fost de 84,7%, fiind similară în cele două loturi (hepatită cronică 88,1% vs. ciroză hepatică 82,6%). Nu s-au constatat diferenţe semnificative între grupul cu ciroză hepatică Child A (85,7%) faţă de grupul cu ciroză hepatică Child B/C (76,5%). Singurul parametru corelat cu rata eradicării a fost nivelul de ALT: la pacienţii cu nivelul ALT mai mic decât dublul valorii normale, rata eradicării a fost mai înaltă, sugerând astfel că eradicarea infecţiei cu *H. pylori* este condiţionată de gradul de inflamaţie necrotică de la nivel hepatic. Autorii au concluzionat că tratamentul de eradicare a infecţiei cu *H. pylori* la pacienţii cu afecţiuni hepatice este eficient şi sigur (23).

Un alt studiu prospectiv realizat într-un centru terţiar din Atena şi desfăşurat pe o perioadă de 7 ani, a evaluat 365 de pacienţi consecutivi diagnosticaţi cu ciroză hepatică. Ulcerul peptic a fost decelat endoscopic la 67 de bolnavi, în studiu fiind înrolaţi 30 dintre aceştia, care au fost ulterior testaţi pentru *H. pylori*: 63,3% *H. pylori* pozitivi, 36,7% *H. pylori* negativi. Pacienţii *H. pylori* pozitivi au primit tratament de eradicare (Omeprazol 20 mg x 2/zi, Amoxicilină 1000 mg x 2/zi şi Claritromicină 500 mg x 2/zi) timp de 1 săptămână, apoi Omeprazol 20 mg/zi 3 săptămâni. Pacienţilor *H. pylori* negativi li s-a administrat Omeprazol 20 mg/zi timp de 4 săptămâni. Evaluarea endoscopică s-a efectuat după 4 săptămâni de la terminarea tratamentului, la 12, respectiv 24 de luni. Pacienţii la care nu s-a obţinut eradicarea *H. pylori* au primit cvadruplă terapie 2 săptămâni, apoi Omeprazol 20 mg/zi încă 2 săptămâni. Rata eradicării după prima linie de tratament a fost de 79%, iar după a doua linie de tratament de 95%. Recurenţa ulcerului a fost observată în 17 cazuri (majoritatea – 13 în primul an, 4 în al doilea an). Interesant de semnalat a fost faptul că recurenţa

ulcerului s-a produs în 44% din cazuri în lotul pacienţilor *H. pylori* pozitivi trataţi şi 90% din cazuri în lotul bolnavilor cu status *H. pylori* negativ. Autorii subliniază ca eradicarea infecţiei cu *H. pylori* nu previne recurenţele ulcerului peptic la toţi bolnavii cirotici şi propun un tratament de lungă durată cu Omeprazol în toate cazurile, indiferent de statusul *H. pylori* (24).

Pe de altă parte, Villalan şi col. au arătat că eradicarea infecţiei cu *H. pylori* la pacienţii cu ciroză hepatică nu reduce rata recidivelor ulceroase, ceea ce sugerează că terapia de eradicare nu trebuie aplicată la ciroticii cu ulcer peptic (25).

Recent s-a dovedit că rata de eradicare a infecţiei cu *H. pylori* la bolnavii cirotici ulceroşi este strict dependentă de genotipul CYP2C19, deschizându-se astfel noi perspective asupra selecţiei pentru tratament a acestor pacienţi (26).

CONCLUZII

Deşi ulcerul peptic este mai frecvent la pacienţii cu ciroză hepatică, relaţia dintre *H. pylori* şi ulcerul peptic dezvoltat la pacienţii cirotici este incomplet elucidată, rezultatele studiilor publicate fiind heterogene şi contradictorii. Disfuncţia hepato-celulară constituie un factor suplimentar de agresiune asupra mucoasei gastro-duodenale la care se sumează factorii ulcerogeni clasici, inclusiv infecţia cu *H. pylori*.

Majoritatea datelor din literatură afirmă o rată înaltă de eradicare a infecţiei cu *H. pylori* la pacienţii cu ciroză hepatică şi ulcer peptic, tratamentul de eradicare fiind eficient şi sigur. Cu toate acestea, eradicarea infecţiei cu *H. pylori* nu previne recidivele ulceroase la toţi pacienţii cirotici, fiind necesară terapia cu inhibitori de pompă de protoni de lungă durată în toate cazurile, indiferent de statusul *H. pylori*.

PHYSICIAN-PATIENT COMMUNICATION IN CHRONIC DISEASES (Abstract): Chronic diseases represent an important public health issue, given that for many years they are the main cause of death worldwide and the specialists foresee they will soon become the main cause of disability as well. In this paper, the authors analyze the particularities of communication between physicians and patients with chronic diseases, the bidirectional nature of the physician-patient relationship, as well the barriers in establishing an effective relationship, together with the solutions in each case. Patients with chronic disease are particularly special, so that a very important element in the management of their disease is the communication they have with their physicians. Effective physician-patient communication is known to increase the adherence of the patient to the proposed treatment, to help the physician in establishing faster the correct diagnosis and in obtaining better therapeutic result, this leading to professional satisfaction. The effective relationship will have a positive impact over the medical system as well, as the admission in the hospital will be shorter, and, consequently, the costs will be lower. Anxiety, fear or unrealistic expectations of the patient, together with the large amount of work of the physician, his fear of litigation, of physical or verbal abuse from the patient are some of the most important barriers that can be managed to improve the quality of the medical act. The skills needed to communicate effectively with the patient must be learnt, as people do not born with them, and they can be acquired through postuniversitary training. Education of the patients is another issue that must be accomplished to obtain an effective physician-patient relationship, as they will become real partners in their own medical care. **Keywords**: PHYSICIAN-PATIENT COMMUNICATION, CHRONIC DISEASE, BARRIERS, THERAPEUTIC ADHERENCE.

Chronic diseases are characterized by a slow evolution over a long period of time (1), with the symptoms occurring gradually. These diseases are frequently associated with functional disorders or disability, existing, as well, an increased risk for complications to occur (2). World Health Organization divides chronic diseases in four categories: cardiovascular diseases (such as heart attacks and stroke), cancer, respiratory chronic disease (such as chronic obstructed pulmonary disease and asthma) and diabetes (1).

Currently, chronic diseases are the main cause of death in the world, with ischemic coronary disease and stoke holding constantly the first places in the last 15 years (3). More, it is suggested that the incidence

of these diseases will significantly increase in the next couple of years, to become the leading cause of disability as well (4). As a reaction to these alarming projections, collaborative care gains more and more attention (4), the patient being considered a partner in the decision-making process regarding his/her healthcare (5).

Particularities of the patient with chronic disease

Prolonged evolution of the chronic diseases and delayed symptom occurrence explains why these diseases are diagnosed usually in elderly, life stage associated with an increased number of comorbidities- the most frequent being the cardiovascular group, as well as with polytherapy (5). More, psychological disturbances- such as depression, often accompany the chronic diseases, increasing in this way the morbidity and mortality, for which diagnosis and treatment of depression becomes critically important (6).

The moment when they find out the diagnosis of chronic disease is very difficult to bear for most of the patients as they feel vulnerable, confused, without control, being in risk to alter the self-image (7). Likewise, patients with chronic diseases are constrained to endure the difficulty of secondary psychological problems, and if we count the social disturbances, the burden becomes even more difficult to endure, the patients being constrained to make changes both regarding the image of their bodies and their future expectances (8).

Most of the chronic diseases require long life treatment, this being an additional stressor both at physical and psychical level, with the risk to precipitate the symptomatology, being therefore necessary a particular attention to these issues, in order to establish the proper treatment.

Patient centered medicine

Although the patient-centered medicine precepts have their roots in Ancient Greek School of Cos, they were not applied since the beginning, being rather preferred the paternalistic type physician-patient relationship, when the physician alone establishes the treatment, in the virtue of his professional knowledge, while the patient is considered the beneficiary of the medical services, without any possibility to be an active part in the decision-making process (9-11). However, in the last years, the emphasis lays on the collaboration between physician and patient and the involvement of the patient in the decision-making process regarding the therapeutic plan (9, 11, 12). This approach has a series of important advantages, like: facilitates the right diagnosis in a short time interval as the patient will cooperate better, and implicitly adequate recommendations for his treatment (6), as well as the patient adherence to therapy with the subsequent improvement of the results (13), increases the patient complacency and decreases the expenses of medical care as the hospital admission time period will last shorter (6). On the other hand, the risks associated to failure in the effective communication process between the physician and the patient often materialize in losing the trust of the patient, which will lead to lack of his adherence to treatment (6).

Physician-patient with chronic disease relationship – a bidirectional relationship

Therapeutic relationship between the

physician and the patient is considered "the heart and art of medicine" (9), and an essential role in building this relation is acknowledged to effective communication between the two protagonists. Starting with obtaining of appropriate medical history and continuing with the choice of the optimum therapy, the physician-patient relationship rests on communication, and the physician's role in improving the evolution of chronic disease is crucial.

In collaborative care, therapeutic relationship is mutual and dynamic, always existing a bidirectional exchange of information (10, 12, 14, 15). Thus, on the one hand is the fundamental information coming from the patient side, regarding his endurance reflected in symptoms (16) and his inner state, anxiety and emotions (15), as well as those regarding the expectations (9), preferences and concerns (16) or the accepted risk level (13). On the other hand, lays the information coming from the physician side, regarding the disease and the treatment (13). This information must be transmitted using an appropriate language, according to the patient capacity to understand the notions, this being an essential aspect to be an active part in the therapeutic process-making (9, 15).

The successful physician- patient communication materialize in an accurate and quick diagnosis, in psychological counseling and appropriate therapy recommendation, with the final aim being the improvement of the patient's health and healthcare. In this way, the patient will gain self-confidence, will be motivated and optimistic regarding his health- essential items, given that the optimum psychological state may lead to improvement of the results (9).

Plato stated almost two and a half millennia ago that "the greatest mistake in the treatment of diseases is that there are physicians for the body and physicians for the soul, although the two cannot be separated". Combining the concerns regarding the physical suffering and the inner distress is vital to build an effective doctor-patient relationship.

More, efficient communication between the physician and the patient helps the former to understand expectations and experience of the patient, as well as the social context in which the latter lives (9).

An important role in collaborative care have also the emotional problems of the patient with chronic disease, assessed during the same effective information exchange, as well as using the cognitive-behavioral principles and combining the communication skills with evidence-based knowledge (4).

To accomplish this challenge, the physician must gain the proper skills, both interpersonal and communication-related, which will later lead to accumulation of the proper information (9).

Benefits of the effective physician-patient communication

There are numerous benefits of the effective physician-patient communication, about to both.

Thus, the patient can regulate his emotions and can understand the medical information, which will allow him to identify his own needs, perceptions and expectations. In this way, the patient will feel he is involved in the therapeutic process and will adhere easier to the proposed treatment, the quality and results of the care will improve, and his satisfaction will increase.

The physician, by combining his profes-

sional training with the interpersonal communication skills will succeed in establishing the right diagnosis in a shorter period and obtain better therapeutic results, which will lead to professional satisfaction, decrease in the stress level and decreased exhaustion risk.

Not least, effective physician-patient communication, quick diagnosis and patient's adherence to therapy has a positive impact over the medical system, as the admission in the hospital will be shorter, and, consequently, the costs will be lower (9).

Patient's adherence to treatment assumes more than his simple compliance to therapy, being the result of his direct involvement in establishing the therapeutic plan. When the patient is asked about different ways to manage his disease, he will feel more responsible and will follow easier the recommendations regarding the medication, diet or life style (5, 17).

Therefore, the characteristics of the effective physician-patient relationship include a relaxed environment for the medical interview, discussing various therapeutic options and the regimen which is to be put into practice, as well as scheduling the check-up visits- to assess the efficiency of the administered therapy according to the way the disease will evolve (17).

The physician must pay attention when he seeks words to be used during the discussion with the patient. Communication assumes also non-verbal language, so that the attitude, gestures, and mimic, will have at least the same influence in the transmission of the information (15). When the physician communicates as the patient expects, the latter will be more willing to provide the information required to establish the right diagnosis (incomplete information from the patient may delay and negatively influence establishment of the diagnosis as well as the evolution of the disease), to follow the medical recommendation, to adhere the prescribed treatment (9). All of these will finally result in: recovery (18), increased pain tolerance, decrease in tumor growth, improvement in the mental health and a shorter hospitalization (9).

In a therapeutic relationship based on effective communication the patient could understand the prognosis of his disease, the aim of the care, the expectations regarding the evolution of the disease and the necessity of his own involvement in the treatment (19, 20). These aspects are likewise important for the situation when it is a need to establish the end-of-life treatment, an issue that may have a significant influence over the disease (10, 12, 21), especially because in some chronic disorders dementia sets earlier, and if hypoxia is added, will result a cognitive decline, which becomes more and more severe with aging (5). Therefore, in order to facilitate the establishment of treatment in the event of severe degradation of the decisional competence of the patient along with evolution of the chronic disease, a pro-active attitude it is needed by approaching this subject before the installation of the physical and cognitive decline: identification of medical issues that might occur during the evolution of the disease, the attitude that must be approached in different moments in time and building a therapeutic individualized plan (10, 22).

The communication skills of the physician will lead to an increased self-confidence regarding the patient's participation in discussions related to his disease

and the healing process (18).

Communication skills regard alike the content of the information and the way it is transmitted and received, including: skills for careful and active listening, empathy, using open answer questions (9), clarifying the psychological issues, positive body language (15), supporting the patient to verbalize the emotions, exploring the patient's perspectives (6).

Frequent meetings between the patients and their physicians provide the latter multiple opportunities to optimize the communication relationship, to monitor the treatment or to detect new medical issues, related or not with the initial disease. Information exchange should focus on building up a partnership and counseling the patient.

In order to gain the battle with the disease, the patient needs to be acquainted with it, needs to know how it acts, who is helping it and its weak points, a precious ally in this endeavor being the doctor himself.

Barriers in establishing a therapeutic relationship

A series of barriers may hinder the establishing of a therapeutic relationship between the physician and the patient with chronic disease. These may come from the side of the patient, such as anxiety, fear or unrealistic expectations, or from the side of the physician, generated by the large amount of work, fear of litigation, fear of physical or verbal abuse from the patient (9), discouraging patients to express their fears, concerns, expectations or asking for additional information (13).

It is thus created a vicious chain: if the patient does not have all the information in his terms, if he does not express his concerns, the therapeutic plan is at risk to fail (13). More, there is the risk that patient who is not pleased regarding the communication he had with his physician, to accuse the latter more often for malpractice when the result of the therapy is not the expected one, and more, not for lacking medical knowledge, but for gaps in communication (9, 23)

The moment when the patients find out the diagnosis of their chronic disease, wears the burden of deep feelings: emotion, concerns regarding the disease, shock etc., so that there is a risk that these feelings will monopolize the thoughts of the patient, making him to forget most of the information received, the more so as his cognitive state is damaged (8). These issues are additional barriers in communication and have a negative impact towards understanding the disease, being often associated with non-adherence to therapy (5, 8).

Solutions to establish a therapeutic relationship

There are some solutions the physician can bring forward to support the patient with chronic disease. They regard provision of printed information, for example flyers, provided that the language is appropriate, and the patient can read them. Likewise, if the patient agrees, instruction can be forwarded to family members that wish to be part of the therapeutic plan (8). Before ending the medical visit, the physician should make sure that the patient understood the information received by revising the notions, which will be resumed and strengthened in every subsequent check-up (5, 8, 20). Provision of the medical information both verbally and written increases the chances that the patient will follow the

recommendation (5, 20). Depending on the education level of the patient and his desire to find out additional information, the physician may recommend various other genuine resources, such as books, websites or support groups, where the information is explained using appropriate language. Some studies show that the possibility to contact the physician off work through email or telephone improved the physician-patient communication and the latter's adherence to therapy (7). Likewise, another encouraging element in facing the disease might be the case presentations of various famous people who survived with the same disease or the results of reliable studies in this field (24).

Even though in an effective therapeutic relationship discussion between the patient and his physician should emphasize the understanding of notions related to the course of the disease, its impact on the patient's life, the risks and benefits of each therapeutic option, many of the medical interviews are encumbered by a technical language, difficult to be understood by the patient (20). To be truly helpful for the patient, medical information should be complete, including the aim, the manner and schedule for administration, and possible side effects of the therapy. In this way are eliminated misunderstandings related to the medication administration, and chances for adherence to the therapy will increase accordingly (5). Moreover, information should be provided correctly and promptly, adjusted to the medical condition, patients' needs and preferences. The patient and his family will thus face better the diagnosis, will become aware of the available supportive measures, while the doubt and suffering will proportionally decrease (25).

As the disease worsens, the patient will adapt more and more difficult, will be overwhelmed by negative feelings, such as: physical and psychical helplessness, decreased self-esteem, independence and hope, fear facing the disease, concerns regarding the decreased capacity to cope with the disease, which will lead to decreased ability to decide and seek for the needed support (8, 26). In supporting the patients, the physician may offer explanations regarding how the disease progress, explanations regarding the interpretation of the laboratory investigation results and therapeutic plan, all these leading in the end to a diminished impact of the disease towards the patient (5).

In building the therapeutic relationship between the physician and the patient with chronic disease, the focus should also be on the education of the patient, as an integral part of a therapeutic whole: increasing the level of knowledge about his disease and effective implication of the patient in the management of his own disease. This will result in improving the quality of life, the independence and the degree of (re)integration in society, elaboration of a plan to modify the life style and helping the patient to accomplish these changes (24).

Communication skills can be learned

Communication skills are not innate, nor accumulated along with the clinical experience. They can, however, be learned and will remain embedded by continuous practice (6, 9, 11). Ideally, the process of learning these skills starts in the first years after entering the faculty (4, 9), and they will be supplemented along the professional life by participation in postgraduate courses, for example. The educational pro-

cess dedicated to learning physician-patient communication skills must focus on the practical aspect. For this purpose, role play can be very useful, with or without actors mimicking patients. Some special techniques can be useful in the educational process, such as: WEMS (Waiting, Echoing, Mirroring, Summarizing) and NURSE (Naming, Understanding, Respecting, Supporting, Exploring) (6).

Physician's and patient's opinion towards successful communication do not always overlap, the physician having the tendency to overestimate his own communication skills. Thus, a study performed by Tongue *et al.* shows that 75% of the surveyed orthopedic surgeons were satisfied by the manner they communicated with their patients, while only 21% of the patients were content of the communication they had with their physicians. More, the patients tend to assess the professional capacity of their physician also in the view of the latter's ability to transmit information regarding the disease their patients suffer of and the proposed therapeutic plan (9).

CONCLUSIONS

Nowadays, the chronic diseases represent the main cause of mortality and morbidity across the world, with a prediction that their incidence will significantly increase. To effectively manage his disease, the patient suffering of a chronic disease should learn to live with it and adjust his life style in a manner that will ensure a better evolution of the disease. Physician-patient communication represents a key element in accomplishing this essential desideratum.

The benefits of effective communication between the physician and the patient are well known and studied, these having a serious impact both over the medical aspects which reside mainly in a favorable evolution, as well as over the psycho-emotional aspects, which have many times an important impact on the patient with chronic disease.

Effective communication between the physician and the patient assumes, on the one hand, building up communication skills during the academic and postuniversitary training of the physicians, so that they will be able to effectively combine the medical knowledge and the empathy and emotional support offered to their patients, and on the other hand education of the patients so that they will become real partners in their own medical care.

DISLYPIDEMIA AS A RISK FACTOR FOR CARDIOVASCULAR DISEASE (Abstract): The aim of the study was to evaluate dislypidemias as risk factor in the countryside. **Material and method**: There have been evaluated 413 patients from the countryside (Jorăşti, Galaţi County), in the period 2008-2010. There was performed history taking, physical examination, an ECG and biological findings (glycemia, colesterolemia, HDL-colesterolemia, trygliceridemia, creatinenemia). **Results**: In these patients there was noticed a higher prevalence of the dislypidemias in women (65.7%) than in men (50.29%). Both dislypidemias and hypertension were more frequent in patients with cardiovascular disease or in those with high risk of cardiovascular disease than in those with a small or absent risk both in men and in women. In 208 cases there have been present all the elements of the metabolic syndrome. **Conclusions**: The modifiable risk factors have a very important part in the development of cardiovascular diseases in the countryside. Using proper programmes of prophylaxis there can be hope for a decrease of the morbidity and mortality of cardiovascular disease. Key words: CARDIOVASCULAR RISK FACTORS, DYSLIPIDEMIAS, CARDIOVASCULAR DISEASE

Dislipidemiile cuprind totalitatea modificărilor calitative şi cantitative ale lipidelor din sânge (creşteri sau scăderi). În practica medicală termenul este restrâns la hiperlipidemiile care sunt însoţite şi de scăderea Col-HDL. Hiperlipidemiile reprezintă creşterea în sânge a colesterolului şi/sau trigliceridelor peste valorile normale. Valorile normale reprezintă o medie statistică populaţională şi corespund la cea mai scăzută mortalitate şi morbiditate cardiovasculară. Colesterolul circulant are rol central în patogeneza aterosclerozei (1,2).

Dislipidemia este un important factor de risc cardiovascular, iar în cele mai multe situaţii, ea se însoţeşte de diabet zaharat, obezitate şi hipertensiune arterială (entităţi reunite în sindromul metabolic). Studiile recente au subliniat implicarea dislipidemiilor în afecţiuni nu doar din sfera cardiologiei, diabetologiei, nutriţiei ci şi în patologii din sfera gastroenterologiei, hepatologiei, nefrologiei, reumatologiei, neurologiei şi bolilor infecţioase.

Studiile observaţionale au demonstrat că reducerea incidenţei a principalilor trei factori de risc majori, fumat, dislipidemie şi hipertensiune arterială este responsabilă de peste 50% din reducerea mortalităţii cardiovasculare.

EVALUAREA RISCULUI CARDIOVASCULAR

Bolile cardiovasculare reprezintă în continuare prima cauză de morbiditate şi mortalitate în ţările civilizate. Riscul cardiovascular este reprezentat de totalitatea acţiunii factorilor care produc boli cardiovasculare aterosclerotice. Prin controlul acestor factori pot fi influenţate aterogeneza şi consecinţele

ei clinice : cardiopatia ischemică, boala cerebrovasculară şi arteriopatia periferică (3,4).

Factorii de risc cardiovascular :

1. Stilul de viaţă : dietă aterogenă (bogată în grăsimi saturate, colesterol şi calorii), fumatul (> 10 ţigări/zi), excesul de alcool, sedentarismul, stresul psiho-social
2. Vârsta : bărbaţi > 45 ani, femei > 55 ani sau postmenopauză
3. Istoric familial de cardiopatie ischemică sau alte boli cardiovasculare cu instalare precoce (< 55 ani pentru tată sau frate şi < 65 ani pentru mamă sau soră)
4. Caracteristici biochimice şi fiziologice : hipercolesterolemie (creşterea Col-LDL > peste 130 mg/dL), Col-HDL < 40 mg/dL (< 1 mmol/L) pentru barbaţi şi < 50 mg/dL pentru femei ; hipertrigliceridemie > 150 mg/dL ; hipertensiune arterială (chiar controlată medicamentos) ; diabet zaharat ; obezitate.

La evaluarea riscului cardiovascular poate fi eliminat un factor de risc în cazul în care Col-HDL > 60 mg/dL (1,6 mmol/L).

MATERIAL ŞI METODĂ

Lotul de studiu a cuprins un număr de 413 pacienţi din mediul rural care s-au prezentat la CMI Dr. Anghel Lucreţia- Joraşti , judeţul Galaţi în perioada 2008-2010.

Evaluarea pacienţilor s-a făcut prin :

I Anamneză – a cuprins întrebări privind :

1. vârsta, sexul, starea civilă, nivelul de instruire, ocupaţia
2. antecedente heredo-colaterale : deces prin boală cardiovasculară sub 55 de ani, cancer diagnosticat sub 65 de ani, diabet zaharat, hipercolesterolemie familială
3. antecedente personale patologice : existenţa de boli cronice, boli cu transmitere sexuală, intervenţii chirurgicale, medicaţie relevantă
4. stilul de viaţă : alimentaţia, consumul de alcool, activitatea fizică, fumatul

II. Examenul clinic obiectiv – inclusiv măsurarea înălţimii şi a greutăţii, a taliei, a perimetrului abdominal, (pentru obezitatea abdominală, normal sub 94 cm la bărbaţi şi 80 cm femei) calcularea indicelui de masă corporală, măsurarea tensiunii arteriale (3 valori la interval de 5 minute) şi a pulsului

III. Investigaţiile au cuprins : EKG, glicemie, colesterolemie, HDL-colesterolemie, trigliceridemie, creatininemie, sideremie.

REZULTATE ŞI DISCUŢII

Boala cardiovasculară este responsabilă de 17 milioane de decese în fiecare an. Specialiştii estimează că în zece ani numărul deceselor va ajunge la 25 de milioane pe an. Potrivit studiului EuroAspire III, 2, 50% din totalul deceselor din Europa sunt provocate de bolile cardiovasculare. România se afla în primele 4 locuri în lume în ceea ce priveşte mortalitatea de cauză cardiovasculară. Riscul de apariţie a bolii cardiovasculare la populaţia adultă din România în următorii 10 ani este de 3,5%.

Pe linia aceloraşi eforturi de prevenţie , studiul nostru a urmărit evidenţierea rolului important pe care dislipidemiile îl joacă în apariţia bolilor cardiovasculare.

Repartiţia pe sexe a pacienţilor peste 60 de ani incluşi în studiu

Din studiile efectuate pe lotul de pacienţi se obsevă că valorile colesterolului total sunt în medie mai mari la femei (65,70%) decât la bărbaţi (50,29%).

Atât femeile câ şi bărbaţii cu boală cardiovasculară prezentă şi cu risc crescut de boală cardiovasculară prezintă valori ale colesterolului mult mai mari faţă de cei cu risc scăzut sau fără risc de boală cardiovasculară. Din totalul de 413 pacienţi bărbaţi şi femei, 110 sunt cu boală cardiovasculară prezentă iar dintre aceştia 74 (62,27%) sunt cu valori crescute ale colesterolului. Din totalul de 413 pacienţi 65 sunt fară risc de boala cardiovasculară, iar dintre aceştia 9 pacienţi sunt cu valori crescute ale colesterolului.

Se observă în lotul de femei o prevalenţă

PACIENȚI FEMEI	NR. PACIEN?I	TA		COLESTEROL TOTAL		HDL COLESTEROL			TRIGLICERIDE		
		HTA	TA normală	Val. normale	Val. crescute	Val. normale	Val. crescute	Val. scăzute	Val. normale	Val. crescute	Val. scăzute
CU BOALĂ CARDIOVASCULARĂ PREZENTĂ	67	40	27	16	51	62	3	2	58	7	2
CU RISC CRESCUT DE BOALĂ CARDIOVASCULARĂ	72	60	72	12	60	64	5	3	63	9	0
CU RISC SCĂZUT DE BOALĂ CARDIOVASCULARĂ	67	20	47	22	45	60	3	4	59	6	2
FĂRĂ RISC DE BOALĂ CARDIOVASCULARĂ	36	4	32	33	3	32	0	4	36	0	0
TOTAL PACIENȚI	242	124	118	83	159	218	11	13	216	22	4
		54,24%	48,76 %	34,30 %	65,70 %	90,08 %	4,55 %	5,37 %	89,26 %	9,09 %	1,65 %

PACIENȚI BĂRBAȚI	NR. PACIEN?I	TA		COLESTEROL TOTAL		HDL COLESTEROL			TRIGLICERIDE		
		HTA	TA normală	Val. normale	Val.crescute	Val. normale	Val.crescute	Val. scă zute	Val. normale	Val. crescute	Val. scăzute
CU BOALĂ CARDIOVASCULARĂ PREZENTĂ	43	16	27	20	23	41	0	2	34	8	1
CU RISC CRESCUT DE BOALĂ CARDIOVASCULARĂ	86	50	36	33	53	74	5	7	76	8	2
CU RISC SCĂZUT DE BOALĂ CARDIOVASCULARĂ	13	1	12	9	4	10	1	2	12	0	1
FĂRĂ RISC DE BOALĂ CARDIOVASCULARĂ	29	7	22	23	6	27	2	0	28	1	0
TOTAL PACIENȚI	171	84	97	85	86	152	8	11	150	17	4
		49,12 %	56,73 %	49,71 %	50,29 %	88,89 %	4,68 %	6,43 %	87,72 %	9,94 %	2,34 %

ridicată a hipercolesterolemiei atât în cazul pacientelor cu afecţiuni cardiovasculare prezente (76,1%), cât şi în cazul celor cu risc crescut de boală cardiovasculară (83,3%).

Asocierea cu hipertensiunea arterială este de asemenea semnificativ mai importantă la pacientele cu boală cardiovasculară (59,5%) şi la cele cu risc crescut de boală cardiovasculară (83,3%), faţă de cele cu risc scăzut (asociere de 29,8%) sau absent (asociere de 11,1%).

În cazul bărbaţilor se observă de asemenea o prevalenţă ridicată a hipercolesterolemiei la pacienţii cu boală cardiovasculară prezentă (53,5%), precum şi la cei cu risc crescut de boli cardiovasculare (61,6%), dar corelaţia este mai mică decât în cazul femeilor.

De asemenea în cazul lotului de bărbaţi asocierea cu hipertensiunea arterială este semnificativ mai importantă la pacienţii cu boală cardiovasculară (37,2%) şi la cei cu risc crescut de boală cardiovasculară (58,1%), faţă de cei cu risc scăzut (asociere de 7,5%) sau absent (asociere de 24,1%).

Frecvenţa mai mică a dislipidemiei şi a hipertensiunii la pacienţii de sex masculin cu boli cardiovasculare sau cu risc de boli cardiovasculare faţă de pacienţii de sex feminin este legată probabil de existenţa asocierii mult mai importante la lotul de bărbaţi cu ceilalţi factori de risc (fumat, consum de alcool)

Riscul de a dezvolta disfuncţie endotelială creşte cu numărul factorilor de risc prezenţi.

În funcţie de antecedentele heredocolaterale :

- Deces prin boală cardiovasculară la rude de gradul I-II : 2 cazuri la bărbaţi şi 17 cazuri la femei
- DZ tip 2 la rudele de gradul I – II : 4 cazuri la bărbaţi şi 11 cazuri la femei
- Hipercolesterolemie familială la rudele de gradul I – II : 1 caz la femei

Într-un număr de 208 cazuri pacienţii au prezentat sindrom metabolic, cu o frecvenţă mai mare la femei 124 (59,62%) şi 84 bărbaţi (40,38%).

În 89 de cazuri pacienţii au prezentat asocierea de multipli factori de risc : fumat, hipertensiune arterială, HDL < 40 mg/dL, istoric familial de boală cardiacă ischemică (BCI) precoce (BCI < 55 ani la rude de sex masculin şi BCI < 65 ani la rude de sex feminin), vârsta (bărbaţi > 45 ani, femei > 55 ani)

Studiul demonstrează importanţa factorilor de risc modificabili în apariţia bolii cardiovasculare. El se aliniază eforturilor concertate ale specialiştilor români ce urmăresc scăderea mortalităţii cardiovasculare cu 10% în următorii cinci ani. Este necesară elaborarea unei strategii care să îmbine atitudinile individuale (evaluare, stratificarea riscului cardiovascular, aplicarea intervenţiei, reevaluarea rezultatelor) cu cele populaţionale (accesibilitate crescută la măsurile de prevenţie cardiovasculară), având drept obiectiv fundamental reducerea morbidităţii şi mortalităţii cardiovasculare (5).

Unele măsuri pe care ţări vest-europene le-au adoptat şi la care medicii de familie din ţara noastră s-ar putea ralia cu succes sunt :

- realizarea de cercetări naţionale şi internaţionale privind nutriţia şi bolile cardiovasculare
- integrarea în serviciile de sănătate, în special cele primare, a recomandărilor privind o alimentaţie corectă şi echilibrată
- implementarea de programe de promovare a unei alimentaţii corecte
- programe de informare în şcoli şi instituţii educaţionale
- realizarea unui sistem de monitorizare a comportamentelor privind sănătatea, factorii de risc, nutriţia, bolile şi mortalitatea la nivelul populaţiei (6,7,8).

CONCLUZII

Studiul demonstează rolul foarte important jucat de factorii de risc modificabili

pentru apariţia bolilor cardiovasculare la populaţia rurală din România.

Atât femeile cât şi bărbaţii cu boală cardiovasculară prezentă, cât şi cei cu risc crescut de boală cardiovasculară prezintă valori ale colesterolului mult mai mari faţă de cei cu risc scăzut sau fără risc de boală cardiovasculară.

Hipertensiunea arterială este mai frecventă la pacienţii cu boală cardiovasculară cât şi cei cu risc crescut de boală cardiovasculară faţă de cei cu risc scăzut sau absent. Aceasta oferă speranţa că prin măsuri adecvate de prevenţie se poate obţine o scădere a incidenţei bolilor cardiovasculare şi deci a morbimortalităţii asociate.

NOUTĂŢI

STUDIUL TOXICITĂŢII EXTRACTULUI APOS DE *TRIGONELLA FOENUM-GRAECUM*

Utilizarea plantelor medicinale în terapie este o practică frecventă în ţările în curs de dezvoltare. Pentru multe dintre aceste plante lipsesc informaţiile privind posibilele efecte adverse. Prezentul studiu evaluează toxicitatea seminţelor de schinduf (*Trigonella foenum-graecum* (L.)) la animale de experienţă gestante. Extractul apos liofilizat obţinut din seminţele speciei a fost administrat în doze de 500 şi 1000 mg/kg/zi unor femele gestante de şoarece pe parcursul întregii perioade de gestaţie. S-au observat o scădere în greutate a fetuşilor, o creştere a ratei de mortalitate a fetuşilor, precum şi o creştere a incidenţei malformaţiilor fetale. Seminţele de *Trigonella foenum-graecum* (L.) influenţează negativ funcţia de reproducere şi au potenţial teratogen (Khalki L, Ba M'hamed S, Bennis M, Chait A, Sokar Z. Evaluation of the developmental toxicity of the aqueous extract from *Trigonella foenum-graecum* (L.) in mice. *J Ethnopharmacol* 2010 ; 131 : 321-325).

FIGHTING FOR A SUCCESSFUL AGEING

"Who wants to live forever?" and Freddie Mercury were in our minds and our hearts more than thirty years ago. Of course, it meant something completely different than now. Well, I do not know about "forever" but most of us would want to live longer and, at the same time, to enjoy life as much as possible without any burden associated with old age. We want to live longer but with the same physical and mental strength as in our younger years, we want to enjoy ourselves with the same intensity as we used to, and we want to stay as far away as possible from diseases, disabilities, and dependence.

This trend of thought is increasingly popular as the number of elderly increases, being of great interest not only for the beneficiaries but also for the medical and social services. The response to this increasing demand has been developing over the last twenty years as a general concept with several denominations: healthy ageing, successful ageing, positive ageing, ageing well, ageing productively (1).

The broad concept of active and healthy ageing was proposed by the World Health Organization (WHO) as the process of developing and maintaining functional ability that enables wellbeing in older age (2). On a broader scale, healthy ageing means optimizing opportunities for physical, social and mental health to enable older people to take an active part in society without discrimination and to enjoy an independent and good quality of life. It means considering the concepts of independence, autonomy, purposeful and meaningful existence, and the opportunity to participate and contribute. To fulfill these aspirations, people need to maintain adequate physical and mental health status (3, 4).

But it is not that simple as it sounds. It is well documented that ageing is influenced by genetic factors and modifiable factors (that we can safely rename as our own lifestyle-dependent factors). Rethinking our lifestyle from the earliest period of our life is really the best start for a healthy ageing. But what can be done for those who "missed the starting gun" and are facing, in older age, this terrible challenge-changing life-time habits (most of them being the very source of self-enjoyment-good food, good wine, a cigarette or two, lazy Sunday afternoons) with new, healthier habits, most of them totally hateful-untasty food, water instead of wine, no cigarettes whatsoever and a lot of exercise, usually in terrible weather or embarrassing attempts to do aerobics.

When to start? Where to start? The good news is that it is never too late - the challenge is how to do it and actually enjoying it at the same time.

Normal ageing is intimately related to two very important phenomena that we must face and should fight, sarcopenia and obesity, and it is widely believed that first important steps in healthy ageing mean a good understanding of these two elements.

Sarcopenia is an age-related process of skeletal muscle loss associated with declining physical performance. It was first described by Rosenberg in 1989, who gave it

the name from the Greek "sarx" = meat and "penia" = loss (5). It is highly prevalent among older subjects, reaching 15–24% in 60–70-year-olds, over 50% in subjects aged 80+, and close to 70% in nursing home residents (6). Sarcopenia is associated with a risk of adverse outcomes such as physical disability, poor quality of life and death, which promote it as a major public health problem in the world.

As the studies on sarcopenia multiplied in the last 20 years, they brought to attention that new parameters were needed for a more accurate diagnosis, such as determination of muscle mass, muscle strength and physical performance. New techniques were recommended as golden standard in the diagnosis of sarcopenia instead of the well-known and somewhat warned anthropometric measurements: computed tomography, magnetic resonance imaging, dual energy X-ray absorptiometry, and bioimpedance analysis for the determination of muscle mass, handgrip strength, knee flexion/extension and peak expiratory flow for muscle strength, and short physical performance battery for physical performance. All these tests proved that there is a progressive mismatch between mass and strength that occurs because of a progressive deterioration of muscle “quality”, including decrease in fiber size and number, intrinsic reduction of contractility in the intact fibers, fat micro and macroinfiltration, increase in collagen, modification of the motor unit, and impaired neurological modulation of contraction.

Evidence has also emerged that muscle strength is more important than muscle mass as a determinant of functional limitation and poor health in older age. The loss of muscle strength rather than muscle mass is called dynapenia, and some have argued that the term sarcopenia should be replaced by dynapenia, which is better suited to describe age-associated loss of muscle strength and function.

Determining the most appropriate reference value of muscle mass for the purpose of making a diagnosis of sarcopenia is still an important issue in different populations in the world. To establish low muscle mass, some studies have assessed the total or appendicular skeletal muscle in young adults as the reference value. For a clinically applicable definition, correction factors such as height, body mass index, and body fat have been used, and that brought us back to obesity and its leading part in ageing.

Obesity is defined as abnormal or extensive fat accumulation that negatively affects health. Until recently, its diagnosis was based on the values of Body Mass Index (BMI). However, recent studies pointed out that new parameters, which include measures of body composition, fat and fat-free mass are of greater importance than BMI, and therefore should be determined when diagnosing obesity, especially in elderly population.

It is common knowledge that the association between sarcopenia and obesity, most frequently encountered in the ageing population is an entirely different entity, called sarcopenic obesity, which is associated with higher risk for mortality than sarcopenia and obesity by themselves (7).

These new concepts influenced the physicians’ approach to changing the lifestyle in elderly persons. It is now agreed that keeping a constant, vigorous physical activity will guarantee an improved longevity by decreasing the risk of sarcopenia and sarcopenic obesity, frailty, and chronic diseases. It will also guarantee a better

quality of life as it improves functional health, cognitive functions and reduces the risk of falls and fractures. However, people tend to become less active as they get older and even less active if they have chronic dyspnea or chest pain or osteoarticular problems. Evaluating the degree and type of physical activity that the patient qualifies for and fitting it into patient's type of life is vital and it requires a good relationship with the patient who should be convinced of the benefits of these alterations in his/her life (8).

It is also a well-known fact that good eating habits and healthy foods are keys for staying healthier for longer. Many of the diseases that torment elderly people are the results of dietary factors, some of them acting since childhood. Education and a healthy diet since infancy tend to promote and maintain healthy habits throughout the rest of our life (9).

How easy is to change old (and pleasant) eating habits in later life? With old age there will be different nutritional requirements and fighting cachexia and sarcopenic obesity should become one of the main goals. Combining specific nutritional needs with restrictive diets for the inevitable metabolic and cardiovascular diseases and making them look good is almost a "bridge too far".

Even considering the inevitable cognitive and psychological changes among old people, everybody wishes to remain useful, alert and socially interconnected. But the barriers are innumerable: retirement, age discrimination, neglect, abuse in all its forms, etc. Sustained education should promote better ways of using the huge amount of energy and lifelong experience the elderly people have. Health and social programs should promote and actively increase the employment of elderly people either in their own field, by training and transferring knowledge and experience to younger generations, or in new jobs that would require small investments in retraining (10).

Involving older people in volunteering activities is another important option, as it helps keeping them useful and avoids social exclusion. Explaining these opportunities to our ageing population would be the main tool we have in promoting healthy mental and functional ageing. We should never forget that the environment helps determine how active older people can be in society-the more accessible and age-friendly the environment, the more active old people can be. Participation in all types of activities builds and consolidates social connections and improves self-esteem and wellbeing.

It is not an easy task to promote and ensure healthy ageing, but the good news is it is not a one-man task, but a multidisciplinary team problem. We age differently, so the goal of the team will be to find personalized recipes that will increase our chances of positive ageing. It is and should be based on a strong and confident relationship between all team members and the patient. If the patient is not fully committed the results will be disappointing no matter how skilled the team is. So, maybe all those of us who are not elderly yet should change a thing or two in our lifestyle and start fighting for a happy and long healthy ageing!

NEWS

OBESITY AND INFLUENZA

Influenza is an infectious disease with self-limiting evolution, with the exception of age extremes and patients with chronic diseases where life-threatening complications may occur. Recent studies have shown the role of obesity in increasing the risk of severe complications of flu infection but also the influence of obesity on flu transmission. Thus, according to an epidemiologic study published in *The Journal of Infectious Diseases* in September 2018, the obesity can prolong the duration of viral shedding which influence influenza transmission. The study was conducted in the period 2015-2017 and included 1783 participants aged between 0 and 92 years. In the study group, the prevalence of obesity was between 2% - 42%, about 6 times higher in adults than in children. The results showed that the mean predicted influenza virus shedding duration was higher in children (7.2 days) than in adults (5.5 days). Also, regardless of the age group, influenza B virus recorded a shedding duration longer than influenza A virus. The same study showed that the influenza A virus shedding duration increased by 40% for symptomatic obese adults (5.23 days) compared to non-obese adults (3.68 days) but has not established any association between obesity and the influenza B virus shedding duration. The researchers motivated the increase in the virus shedding duration by chronic inflammation in patients with obesity due to immune depression. This study confirms the need for measures to prevent and control obesity as well as flu vaccination amongst the population at risk of developing severe complications or death (Maier HE, Lopez R, Sanchez N, Sophia Ng, Gresh L, Ojeda S, Burger-Calderon R, Kuan G, Eva Harris, Balmaseda A, Gordon A. Obesity Increases the Duration of Influenza A Virus Shedding in Adults. *J Infect Dis* 2018; 218(9): 1378-1382).

RESILIENCE - INTERDISCIPLINARY APPROACH AND PERSPECTIVES

RESILIENCE-INTERDISCIPLINARY APPROACH AND PERSPECTIVES (Abstract): Resilience is defined as the ability to maintain or successfully regain cognitive health after facing significant stress. Therefore, this concept helps us understand why some individuals cope with stressful situations much better than others. To explore the concept of resilience, reference should be made to the allied concept of adaptation strategies. In the geriatric population, chronic illness is a common problem that could reduce the impact of coping strategies and resilience, especially when the illness is associated with pain and disability. Depression and functional independence are also correlated with resilience and are important in modulating the subsequent rehabilitation. In the geriatric population, functional recovery after major stress is influenced by many factors. Adaptive ability and frailty play an important role, interacting in determining the final functional status. Acute or chronic stress reduced physical activity, poor nutritional status, and depression can trigger or accelerate frailty. **Keywords:** RESILIENCE, FRAILTY, CHRONIC ILLNESSES.

Definition of resilience in relation to successful ageing

In the literature there is a multitude of different types and definitions of resilience, this term being used in different contexts. In a general sense, resilience has been defined as the psychological ability or capacity of a person to respond to stressful situations (1).

According to the American Psychological Association (APA), resilience is defined as "the process of adapting well in the face of adversity, trauma, tragedy, threats or significant sources of stress" as well as bouncing back from difficult experiences (2). Thus, resilience has been recognized as an important personal attribute in life that contributes to the ability to cope with stress and cultivate cognitive health and wellbeing.

Resilience is a concept that has also gained ground in gerontological research because it has been linked to successful aging and quality of life (3, 4).

As the ability to resist adversity or circumstances that cause a significant decrease in quality of life (3), resilience can be improved and supported by certain protective factors (PFs) that facilitate this process by modifying the effects of risks associated with stress-related conditions (5, 6). So far, several studies have examined the relationship between the various protective factors and resilience. In the studied literature, three such factors have been identified frequently: social support, physi-

cal health and psychological self-efficacy.

With physical activity and lack of disease as components, health, in its turn, can promote and improve resilience, generating a general wellbeing (7). Several studies have found that physical health is reflected in resilience scores (8, 9, 10).

The physical characteristics associated with high resilience include independence in activities of daily living (determined by ADL); daily physical activity/physically active; better physical health; fewer chronic diseases (7).

The study of the relationship between physical health and resilience in the elderly is relevant because functional capacity and health status can decline with age (10).

Rowe and Kahn (11) developed the first theoretical model of successful aging in the late 1990s, a model that included three interactive components: avoiding disease and disability, high cognitive and physical function, and engagement with life. High performance in each of these three areas results in the absence of disease and disability, which leads to the definition of successful aging as "high cognitive and physical functional capacity and active engagement with life". In addition to successful aging, resilience is also associated with health-related quality of life (HRQoL).

Protective factors contribute to support resilience in the process of overcoming adversity, allowing elderly people to age successfully. Including high functional capacity, active engagement and absence of disease and disability, successful aging promotes independence among the elderly (7).

The psychological, physical and social aspects of resilience help overcome age-related stressful situations (12). Thus, psychological resilience is a process of using positive adaptive behaviors when dealing with adversity, such as loss of functional independence due to dementia or depression (13, 14).

From another perspective, at physical level, resilience is the ability to maintain good health and restore the optimal body function when faced with a stressful event, such as after hip fracture (15).

Social resilience is the ability to cultivate, engage in and maintain positive relationships, proving an increased ability to adapt and recover from adverse events and social isolation (8). Recent research suggests that resilience can help override the challenges associated with aging by overcoming hardship despite the adversity (3, 12, 16). The resilience process is outlined by the following model (fig.1).

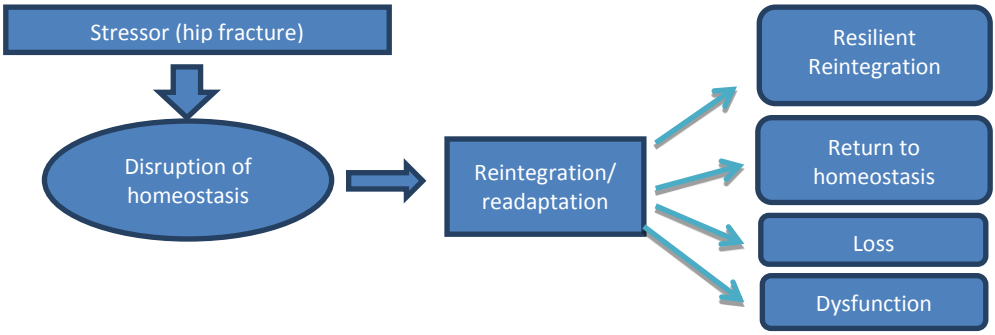

Fig. 1. Resilience model adapted from Resnick B (13). The model outlines the cause and effect pathway of facing adversity, leading to four possible reintegration outcomes. Faced with adversity, homeostasis is disrupted resulting in reintegration. Ideally resilient reintegration is reached, but homeostasis, loss, or dysfunction are possible.

Resilience and frailty

Frailty has been widely used as a term to describe the very old people with disabilities and multiple chronic conditions. It has also been attributed to people living in nursing homes. More recent studies tend to place greater emphasis on the relationship between the concept of frailty and its opposite, resilience (17).

Lekan *et al*. (18) found in their study that participants characterized frailty by such objective physical features as disability, weakness, and balance disorder. In addition, subjective psychosocial aspects, including positive attitudes, social support, and spirituality, motivate in their turn healthy self-care behaviors, thus suggesting that resilience helps prevent frailty by mitigating or reversing its negative effects.

Conditions requiring surgery are particularly stressful for the patient and can interfere with homeostasis. For this reason, the presence of frailty should be evaluated preoperatively and subsequently treated postoperatively. It was found that the prevalence of frailty was much higher among patients undergoing surgery compared to the general population.

Acute and chronic stress, low levels of activity, depression and low nutritional status can initiate or accelerate the frailty status (19).

Techniques for the determination of resilience

There is a large number of scales or tools that have been developed to measure the concept of resilience, a high level of reliability and validity being demonstrated for the Resilience Scale (20).

A comprehensive assessment of resilience scales suggested that Brief Resilience Scale (BRS), Connor-Davidson Resilience Scale (CD-RISC) and the Resilience Scale for Adults (RSA) could provide the best psychometric assessments and the most significant results of the measurements. However, Windle *et al*. (21) determined no true "gold standard" of the measures they evaluated.

Resilience levels among the elderly vary according to the population surveyed and the measurement scale used; a high resilience was reported in the range of 14% -35%.

In a study in adults aged 50 years and over, 14.5% of the sample proved to be very resilient, based on General Health Questionnaires (GHQ-12) scores. The results have shown that high levels of resilience are associated with older age, suggesting that younger old are not always as resilient as those who are older. Increased resilience rate in other studies, using the CASP-19 questionnaire, the 10-item Connor-Davidson Resilience Scale (CD-RISC 10) and GHQ-12 ranges from 31% to 46% (22, 23, 24).

Key characteristics of increased resilience in adults aged 65 years and over, outlined in the literature, include mental, social and physical factors (tab. I).

TABLE I

Key characteristics of resilience

Coping and adaptive models **Gratitude** **Happiness** **Lack of cognitive failure cognitive** **Mental health** **Optimism** **Hopefulness** **Positive emotions**	Communion Contact cu family and friends Self-rated successful aging Social support Social support seeking Strong, positive relationships	ADL independence High mobility Physical health Self-rated successful aging

Resilience in geriatric pathology

With aging, there may be a decline in physical, cognitive and psychosocial activity, and thus an increasing number of seniors suffer from chronic diseases. These patients additionally associate low physical performance, decreased pain tolerance, potential decrease of life expectancy, isolation tendency, and loss of self-confidence (25).

Among the geriatric population chronic illnesses are common and can reduce resilience, especially when these diseases are associated with pain and disability (26). However, in the context of such specific conditions as spinal cord injuries, amputation and neoplasms, some authors believe that the elderly seem more resilient than young people when faced with chronic diseases. This is due to their lived experiences that made them more mentally strong when faced with physical problems (19).

In patients with cardiovascular disease, psychological resilience has been shown to independently predict the physical and mental health-related quality of life, but its relationship with depression has not been examined. Low psychological resilience is associated with depression, especially with its affective features (27, 28, 29).

Older patients (over 65 years) with heart disease have higher resilience than younger patients (< 65 years).

Chronic pain, the most common symptom encountered in medical history, is present in 25% -50% of patients. The most common pain complaints in the elderly are osteoarthritis, especially in the lumbar or cervical region (approximately 65%); musculoskeletal pain (approximately 40%); peripheral neuropathy (35%); and chronic joint pain (15% -25%). Psychological resilience can protect against the adverse effects of chronic pain. However, due to some life circumstances and old age-related challenges (loss of life partner, social exclusion), resilience could work differently in the elderly compared to adults (30).

In their study, Morete *et al.* (31) concluded that the elderly with chronic pain have lower resilience, more severe depression and lower quality of life than those without chronic pain.

Hip fracture, for example, is common in elderly patients and is generally associated with other comorbidities and physiological changes with impact on quality of life. Thus, the concept of resilience can explain why this impact varies among these patients. In their study Rebagliati *et al.* (19) have assessed the relationship between resilience, frailty, and quality of life, and to what extent these factors might affect the postoperative rehabilitation outcome. These factors were analyzed by a multidisciplinary assessment at the beginning and at the end of the rehabilitation program. It has thus been demonstrated that there is a negative correlation between disability and resilience, interacting with the frailty level. Resilience and quality of life are positive predictors of functional status at discharge.

Adaptive capacity interacts with the disease in orthopedic surgery: a low plasticity level predicting a lower degree of rehabilitation in elderly patients with hip fracture.

Depression, satisfaction, and functional independence are also correlated with resilience, being important in modulating rehabilitation outcome, as these personal characteristics can be modifiable during rehabilitation. Thus, resilience plays a significant role in achieving optimal functional rehabilitation in elderly people with hip fracture. The results suggest the introduc-

tion of early routine assessment of resilience in future outcome studies in rehabilitation (32).

CONCLUSIONS

In our observation, multidimensional assessment of the elderly before commencing rehabilitation becomes a necessity. Screening for low adaptive capacity and frailty at the initial assessment allows patients with a low recovery potential to be identified so that each patient to receive a personalized treatment program.

From this perspective, it is very important to evaluate all variables that could affect the performance: cognitive impairment, depression, family support and environment.

Resilience can be an important aspect in the process of fighting chronic pain; its assessment could contribute to a thorough/holistic approach to elderly patients.

Spitalul Clinic de Urgenţe pentru Copii "Sf. Maria" Iaşi

ALLERGIC COMORBIDITIES IN CHILDHOOD BRONCHIAL ASTHMA (Abstract): Bronchial asthma is the most frequent chronic disease of childhood. The association of this disease with allergic rhinitis increases the prevalence and severity of bronchial asthma to 60% compared with 2% in subjects without allergic rhinitis. Food allergy can be expressed in a variety of respiratory symptoms, especially when IgE mediated immune responses are involved. In children, the prevalence of bronchial asthma associated with food induced atopic eczema is 2-8% and respiratory clinical picture can be a component of the multisystem anaphylactic reaction or of chronic respiratory disease like bronchial asthma, serous otitis. The association of other allergic comorbidities, like sinusitis, ocular allergies, lymphoid hypertrophy, sleep obstructive apnoea, leads to the conclusion that allergic bronchial asthma (extrinsic) is a systemic disease, with onset at any age, and the dominant clinical feature depends on the child's genetic pattern. **Key words**: BRONCHIAL ASTHMA, FOOD ALLERGY, ATOPIC ECZEMA, ALLERGIC RHINITIS, OCULAR ALLERGY

Bolile alergice sunt cele mai frecvente boli cronice la populaţia pediatrică, afectând aproximativ 25-30% dintre copii: 15-20% - dermatita atopică, 7-10%- astmul bronşic, 15-20%- rinita şi rino-conjunctivita alergică (1).

Noţiunea de „marş alergic" se referă la istoria naturală a afecţiunlor alergice, care se caracterizează printr-o anumită secvenţialitate în perioada copilăriei sau mai târziu (2). Sensibilizarea alimentară în absenţa manifestărilor clinice este un indicator al predispoziţiei genetice.

Comorbidităţile alergice ale astmului bronşic pediatric sunt: sindromul eczemă/ dermatită atopică (SEDA), rinita alergică şi alergiile oculare.

Alergia alimentară se poate prezenta printr-o varietate de simptome respiratorii, mai ales prin implicarea mecanismelor imune Ig E mediate. Aceste simptome respiratorii, produse prin ingestia sau inhalarea particulelor alimentare din aer, pot fi componente ale reacţiilor multisistemice, anafilactice sau boli respiratorii cronice ca astmul bronşic, otita medie seroasă. Prevalenţa astmului bronşic în alergia alimentară este dificil de apreciat (2-8% la copil).

Epidemiologia relaţiei alergie alimentară--alergie respiratorie poate fi de 3 tipuri:

1. simptome respiratorii în timpul alergiei alimentare cu manifestări clinice cutanate sau gastrointestinale, sugerând manifestări clinice sistemice, până la şoc anafilactic.
2. simptome specifice rinitei alergice induse de alergia alimentară.
3. simptome specifice astmului bronşic in-

TABELUL I
Prevalenţa estimată a alergiei alimentare în reacţiile astmatic-induse

Populaţia studiată	Prevalenţa estimată
Copii cu Astm bronşic	57%
Copii cu alergie la lapte	29%
Aliment ca trigger pentru wheezing în timpul reacţiilor acute	<5%
Copii cu SEDA	17-27%

duse de alergia alimentară (3).

Alimentele responsabile de simptome respiratorii în cadrul anafilaxiei sunt: oul, laptele, arahidele, soia, peştele etc. Detectarea IgE specifice pentru ou la vârsta de sugar se corelează cu specificitate de 97% şi sensibilitate de 50% cu apariţia alergiei respiratorii la vârsta de 7 ani şi reprezintă un marker predictiv pentru atopie, mai bun decât nivelul IgE totale în sângele cordonului ombilical. Creşterea concentraţiilor serice de IgE specifice pentru cel puţin unul din patru alergeni alimentari majori (ou, lapte, soia sau grâu) la vârsta de 1 an se corelează cu sensibilizarea la aeroalergeni la vârsta de 5 ani, iar menţinerea la valori crescute a anticorpilor specifici la vârsta de 2 ani a dovedit capacitate predictivă semnificativă pentru apariţia rinitei alergice şi a astmului alergic după vârsta de 5 ani (4).

O investigaţie recentă pe 5149 de indivizi, majoritatea copii alergici la arahide, a demonstrat prezenţa sindromului funcţional respirator manifestat prin dispnee, wheezing, tiraj intercostal, respiraţie zgomotoasă şi congestie nazală în proporţie de 42-56% din cazuri. Jumătate din aceste reacţii au afectat mai mult de un organ sau sistem, dacă pacienţii erau astmatici, faţă de cei fără astm bronşic (21-33%; $p < 0.001$) (5).

Rinita alergică indusă de alergia alimentară reprezintă 70% din simptomele respiratorii observate la testele de provocare alimentară (6). Rinita alergică tipică, în asociere cu alte manifestări clinice cutanate (SEDA) şi/sau gastrointestinale în timpul reacţiei acute alimentare este rară. Pinnock et al. (citat de 3), au investigat relaţia între ingestia de lapte şi producerea de mucus nazal şi nu s-a putut stabili o corelaţie pozitivă.

Astmul bronşic izolat indus de alergia alimentară este rar întâlnit în practica alergologică, dar relaţia aliment ca factor trigger - astm bronşic a fost frecvent semnalată în cadrul reacţiei sistemice la alimente. O analiză publicată pe 300 de bolnavi cu astm bronşic, cu vârsta cuprinsă între 7 luni şi 80 de ani, a evidenţiat, la 12% dintre pacienţi, istoric de alergie alimentară, iar alimentul, ca trigger inductor de wheezing, a fost prezent la 6 cazuri (2%), toţi fiind copii cu vârsta între 4-17 ani (3). Businco et al. (citat de 7) studiază 42 de copii cu vârsta cuprinsă între 10-76 de luni cu eczemă atopică prin alergie la proteina laptelui de vacă şi demonstrează asocierea astmului bronşic în timpul testului de provocare alimentară la 27% din cazuri. Rezultă că prevalenţa relaţiei aliment - wheezing este mai mare la pacienţii tineri cu boli atopice (tab. I).

Creşterea riscului alergiei respiratorii la pacienţii cu alergie alimentară este demonstrat pentru alergia la ou. Sensibilizarea alergică la ou în copilărie a fost identificată ca factor de predicţie pentru boala alergică a tractului respirator în adolescenţă şi viaţa adultă în 55% din cazuri; dacă este asociat SEDA, valoarea predicţiei creşte la 80%. Răspunsul imun mediat prin anticorpi IgE specifici la aliment este responsabil de simptomele respiratorii. Aceşti anticorpi se leagă de receptorii IgE de mare afinitate ai bazofilelor şi mastocitelor din tractul respirator, cu activare celulară şi degranulare, cu eliberare de citokine pro-inflamatorii, ca histamina, triptaza, leucotriene şi prostaglandine. Aceşti mediatori sunt responsabili de reacţia alergică imediată, caracterizată prin

vasodilataţie, bronhospasm şi hipersecreţie de mucus, care determină simptomatologia clinică. Aceşti mediatori specifici pot contribui şi la reacţia alergică tardivă (întârziată), care apare la 4-8 ore după răspunsul alergic imediat. Mastocitele eliberează mediatori către celulele endoteliale modificând expresia moleculelor de adeziune pentru eozinofile, bazofile şi leucocite. În plus, triptaza poate activa celulele endoteliale, crescând permeabilitatea vasculară. Leucocitele, prin proteaze, distrug ţesuturile, determinând faza tardivă a răspunsului imun. Inflamaţia cronică produce hiperreactivitate bronşică. Celulele T specifice cu memorie contribuie la exacerbările astmatice ca răspuns la acelaşi stimul antigenic alimentar.

Alte simptome respiratorii induse de alimente sunt rare, dar grave. Astfel, inflamaţia alergică a mucoasei nazale poate cauza disfuncţia trompei lui Eustachio şi otită medie seroasă cu exsudat recurent, mai ales în alergia la proteina laptelui de vacă.

Sindromul Heiner (hemosideroza pulmonară indusă de alergia la proteina laptelui de vacă) se caracterizează prin episoade recurente de pneumonie asociate cu infiltrate pulmonare, sângerări gastrointestinale, anemie prin deficit de fier şi insuficienţa creşterii. Acest sindrom rar este asociat cu hipersensibilitate non-IgE mediată la proteinele laptelui de vacă.

Simptomele respiratorii induse de inhalarea alergenelor alimentare sunt rar semnalate la copil, dar se pot produce în timpul gătitului sau al manipulării alimentelor.

În ceea ce priveşte aditivii alimentari, s-a semnalat o prevalenţă de 5% a rinitei în relaţie cu ingestia de glutamat monosodic.

În concluzie, alergia alimentară la un bolnav cu astm bronşic trebuie suspectată în următoarele condiţii:

a) astmul acut este neexplicat şi rezistent la tratament;
b) astmul apare după ingestia unor alimente particulare;
c) copiii cu astm bronşic care asociază şi alte manifestări ale alergiei alimentare (ex. anafilaxie, SEDA).

Punctele cheie în afirmarea relaţiei alergie alimentară – simptome respiratorii sunt:

a) simptomele respiratorii acute induse de aliment sunt tipic asociate cu simptome cutanate şi gastro-intestinale;
b) alergia la ou, lapte, arahide, soia, peşte asociază simptome respiratorii;
c) alergia la ou în copilărie (teste pozitive) are rol predictiv pentru dezvoltarea tardivă de alergie respiratorie şi astm;
d) astmul bronşic indus de alimente este mai frecvent la vârsta pediatrică decât la adult;
e) copiii cu SEDA confirmat prin test de provocare alimentară au un risc crescut de a dezvolta astm bronşic indus alimentar;
f) reacţiile alergice induse de alimente pot creşte hiperreactivitatea bronşică la bolnavii cu astm moderat sau sever, dar fără simptome de astm acut;
g) rolul alergiei alimentare în otita medie seroasă este rar;
h) sunt descrise reacţii astmatice la aditivi alimentari, dar sunt neobişnuite;
i) reacţiile astmatice induse de alergia alimentară, pot fi factori de risc pentru reacţii fatale sau nonfatale sistemice.

Rinita alergică, ca inflamaţie a mucoasei nazale, exprimată clinic prin rinoree anterioară şi posterioară, strănut, obstrucţie şi/sau prurit nazal, reprezintă principala comorbiditate alergică a astmului bronşic pediatric.

Mucoasa nazală şi mucoasa bronşică au asemănări structurale şi funcţionale (8). Deoarece majoritatea bolnavilor cu astm bronşic au rinită alergică, s-a sugerat, pentru asocierea astm bronşic – rinită alergică, conceptul „o cale aeriană unică, o singură boală” (9). Totuşi, nu toţi bolnavii cu rinită alergică au astm şi există unele diferenţe între cele două boli (10). Deseori, asocierea dintre cele două forme de manifestare a alergiei respi-

ratorii nu este diagnosticată, deoarece simptomele sunt mai evidente la un organ.

Procesul inflamator alergic se instalează şi se autoîntreţine prin aceleaşi celule inflamatorii, mediatori şi citokine, având aceleaşi faze ale răspunsului alergic (precoce şi tardiv). Diferenţele majore structurale constau în existenţa unui pat vascular bogat în mucoasa nazală şi a musculaturii netede de la nivelul bronhiilor care au proprietăţi contractile şi impact patogenic în astmul bronşic (proliferare, secreţie de mediatori proinflamatorii şi citokine) (11).

La sugar şi copilul mic, rinita alergică este diagnosticată cu dificultate, deseori fiind confundată cu rinita infecţioasă. Persistenţa simptomelor mai mult de două săptămâni impune diagnostic diferenţial cu o cauză ne-infecţioasă de rinită.

Copilul cu rinită alergică dezvoltă mai frecvent unele complicaţii, ca otita medie seroasă şi rino-sinuzita cronică.

Epidemiologia rinitei alergice este mai puţin studiată. Studiul multinaţional ISSAC (12) apreciază prevalenţa rino-conjunctivitei alergice diferit de la o ţară la alta, cu valori de 0,8- 14,9% la categoria de vârstă 6-7 ani şi de 1,4-39,7% la 13-14 ani. În România, pe teritoriul municipiului Cluj–Napoca, utilizând metodologia ISSAC, au evidenţiat o prevalenţă a rinitei alergice la vârsta de 7 ani de 16,6% şi la 13-14 ani o prevalenţă de 13,6%, prevalenţă subestimată la copil. Rinita alergică s-a asociat cu astmul bronşic la 34%, iar astmul bronşic s-a asociat cu rinita alergică la 61,1% (1). Rinita alergică este un factor de risc pentru astmul bronşic. La sugarul la care diagnosticul de rinită alergică a fost formulat de medic, riscul pentru astmul bronşic la 11 ani este dublu (13).

Alte comorbidităţi alergice sunt otita medie seroasă, sinuzita, eczema, faringita, hipertrofia limfoidă, apneea obstructivă în somn, alterarea vorbirii, conjunctivita.

În anul 1999, Organizaţia Mondială a Sănătăţii recomandă (11):

a. bolnavii cu rinită alergică persistentă vor fi evaluaţi pentru astm bronşic anamnestico-clinic, prin explorări respiratorii şi prin răspunsul la bronhodilatatoare;
b. bolnavii cu astm bronşic vor fi examinaţi pentru depistarea rinitei alergice;
c. strategia terapeutică va fi combinată;
d. tratamentul corect al rinitei alergice scade numărul de exacerbări ale astmului bronşic, scade necesarul de medicaţie antiastmatică şi scade riscul de evoluţie spre remodelare bronşică.

Tratamentul cu glucocorticoizi intranazal poate ameliora simptomele astmatice. Administrarea concomitentă de corticosteroizi intranazali şi inhalaţi scade complianţa la tratament a bolnavilor, dar ameliorează formele severe de boală. Asocierea antihistaminicelor orale anti H1 de generaţia a II-a, ameliorează astmul bronşic la bolnavii care asociază rinita alergică.

Monoterapia cu antileucotriene reprezintă o opţiune terapeutică în formele uşoare de astm bronşic asociat cu rinita alergică. Imunoterapia specifică sublinguală a rino-conjunctivitelor alergice poate preveni apariţia astmului bronşic iar, în astmul bronşic persistent uşor asociat cu rinita alergică persistentă moderată/severă, are efecte favorabile.

Alergiile oculare reprezintă un grup heterogen de situaţii patologice la nivelul ochiului, dintre care doar pentru rino-conjunctivita alergică sezonieră (intermitentă) sau persistentă s-a demonstrat relaţia cu astmul bronşic. Conjunctivita vernală, keratoconjunctivita atopică şi conjunctivita gigantopapilară pot asocia sindromul SEDA sau astmul bronşic.

În concluzie, alergia este o boală sistemică, care debutează la orice vârstă, iar manifestarea clinică dominantă este determinată de particularităţile genetice ale copilului.

NOUTĂŢI

ANTIENDOTELINELE DE TIP A - UN EŞEC ÎN TRATAMENTUL HTA SEVERE

Endotelina 1 (ET-1) este un vasoconstrictor de patru ori mai puternic decât angiotensina II care acţionează prin intermediul a 2 receptori relativ ubicuitari (ET-A şi ET-B). Blocajul acestora a părut a fi o cale promiţătoare în tratamentul HTA. Un blocant specific al receptorilor ET-A, darusentan, a fost încercat, fără rezultate încurajatoare în tratamentul insuficienţei cardiace. În tratamentul HTA mai multe studii au comparat darusentanul cu un placebo. Astfel Studiul HEAT-2 a demonstrat un efect semnificativ, la 6 săptămâni la hipertensivi moderaţi. Studiul DAR-201 a confirmat aceste rezultate pentru 115 pacienţi cu HTA rezistentă. Două noi studii de fază III au fost realizate la pacienţi cu HTA severă : primul, pe 718 pacienţi, a demonstrat un oarecare efect al darusentanului adăugat la triterapia iniţială a subiecţilor, celălalt a eşuat în încercarea de a demonstra, pentru 849 de pacienţi, o scădere semnificativă a valorilor TA la 14 săptămâni. Efectele secundare semnalate au fost de cele tip vasodilatator, asociate cu o hepatotoxicitate dependentă de doza administrată. Deşi s-a dovedit a fi eficace în studii mici de fază II darusentanul nu a demonstrat a avea constant un efect aditiv la hipertensivul sever de fază III, determinând stoparea utilizării sale cu referire la această indicaţie (Enseleit F et al. Darusentan, a selective endothelin A receptor antagonist, for the oral treatment of resistant hypertension. *Ther Adv Cardiovasc Dis* 2010 ; 4 : 231-240).

FOOD PATTERNS IN OBESE PEOPLE (Abstract): **Aim**: The objective of the study was to examine dietary patterns in patients with obesity. **Material and methods**: We evaluated a group of 71 subjects with excess weight, who completed a validated food frequency questionnaire. Analyzing the results of the questionnaire, we were able to determine the average daily food intake. We applied the factor analysis and the cluster analysis on the results obtained from the questionnaire in order to identify the food patterns. We calculated correlation coefficients between pattern scores and clinical and biological parameters. **Results**: Three patterns derived from the analysis of the questionnaire: a traditional pattern characterized by increased intake of soups, sauces, and medium intake of food groups from prudent pattern; a prudent pattern, characterized by high intake of cereals, fats/oils, fish, meat, potatoes, vegetables, medium intake of nonalcoholic beverages, eggs, with low intake of sugar, snacks, alcohol; and a western-like pattern, which included an increased intake of sweets/snacks/alcohol and low intake of food groups from traditional pattern. Men had the tendency to adopt more frequently the traditional pattern, than women. **Conclusions**: In the study group, we identified three food patterns which could help in analyzing food intake in patients with obesity and in promoting a healthy lifestyle. **Keywords**: OBESITY, DIETARY PATTERN, FOOD GROUPS.

Obesity is a complex disease with a high risk of developing insulin resistance and type 2 diabetes. Obesity is a major public health problem that already has epidemic proportions. According to the World Health Organization (WHO), 1.9 billion adults are overweight, of whom 650 million are obese, and the prevalence of obesity is expected to increase in the coming years (1). In Romania, obesity is a worrying problem, with 52.4% of the adult population being overweight among which 21.3% are obese (2); in the region of Moldavia we have previously reported that more than half population in rural areas have excess weight (3). People with obesity are at high risk of developing insulin resistance and type 2 diabetes. Diabetes mellitus, the main non-transmissible chronic illness, has also an alarming increase, and can be a co-morbidity, but often a consequence of obesity (4).

Obesity is a complex disease with social and psychological dimensions that affects all ages, all social backgrounds and all coun-

tries, regardless of their economic development. Obesity is more than a consequence of excess eating and sedentary lifestyle. Failure of weight loss diets requires a more in-depth understanding of energy needs and a more sophisticated analysis of behavioral, hormonal and autonomic responses to weight loss (5). Sleep and microbiota disorders are just two of the many pathogenic causes of obesity (6, 7). The medical consequences of overweight, mainly cardio-metabolic disorders (8), are often outweighed by social aspects (discrimination, stigma, accountability) (9) or those generated by the nutritional approach of the disease itself (10, 11).

Nutritional evaluation consists of anamnestic, clinical, dietetic and biological data (12), but food research is an essential element of this evaluation. The study of food intake is based mainly on validated questionnaires (13), especially those on food frequency, as we used in previous studies in the general population (14) or in individuals with diabetes (15). Food frequency questionnaires (FFQ), as well as other methods used in nutritional epidemiology, have many biases. The study of foods or food groups, detailing component nutrients, cannot give a causal relationship in the etiology of chronic diseases. That is why the studies of food patterns providing a comprehensive view of the interactions and synergies of foods and beverages have become increasingly important and can correlate with health and disease (16). The results from studying these interactions can be used to prevent diseases, by including nutritional recommendations related to food patterns in the general food guidelines (17). The relationship of food patterns with obesity has been much studied all over the world (18), and the method has also been previously introduced in Romania (19).

The purpose of the study was to define food patterns determined by factorial analysis in a group of subjects with obesity.

MATERIAL AND METHODS

We performed an observational study on 71 patients with obesity at the Clinical Center of Diabetes, Nutrition and Metabolic Diseases of "Sf. Spiridon" County Clinical Emergency Hospital from Iasi, conducted between January and November 2016. The inclusion criteria were: adults >18 years, presence of obesity (BMI >30 kg/m^2), type 2 diabetes controlled with diet or oral antidiabetics. The exclusion criteria were: age < 18 years, type 1 diabetes, BMI <30 kg/m^2, type 2 diabetes insulin treated. Dietary data were obtained using a version of the EPIC-FFQ, translated, adapted and validated previously for the Romanian population (13). Our version of FFQ has 130 food items. The subjects completed the FFQ by choosing the frequency for the consumption of the foods included in the list, over the past 12 months (never or less than once a month, 1-2 times per month, once a week, 2-4 times per week, 5-6 times per week, once a day, 2-3 times per day, 4-5 times per day, 6 times per day). Then, the completed FFQs were analyzed by the FETA-Software, from which the average daily intake of nutrients (carbohydrates, proteins, lipids, MUFA, PUFA, SFA, vitamins, minerals) and energy was obtained. We used in our analysis 13 food groups, measured in grams.

We also collected socio-demographic data, anthropometrical indices: weight, body mass index (BMI), waist circumference (WC), blood pressure (BP), biological parameters: total cholesterol, low-density lipoprotein-cholesterol (LDL), high-density lipoprotein-cholesterol (HDL), triglycerides, alanine aminotransferase (ALAT), aspartate aminotransferase (ASAT), gamma-glutamyl transferase (γGT), C-reactive protein (CRP), fibrinogen. Subjects were weighed using a calibrated scale and measured with a stadi-

ometer. BMI was calculated by the formula: weight over height (in meters) squared. Eligible subjects were those with BMI over 30 kg/m^2, according to WHO criteria. In addition, BP and WC were measured (normal values for WC were <80 cm in women and <94 cm in men).

For statistical analysis we used descriptive tests, t-independent test, Pearson correlation coefficients. A *p* value of <0.05 was considered statistically significant. Factorial analysis (principal component analysis - PCA) was used to identify food groups that inter-correlated and formed certain patterns. To verify the applicability of PCA, Kaiser-Mayer-Olkin (KMO) and Bartlett Sphericity Test (BTS) were applied. The number of patterns was determined by considering load factor values greater than 0.3. Cluster analysis was performed to group the subjects into exclusive dietary patterns, based on their adherence to the dietetic components identified by PCA. The database was developed and analyzed in SPSS 20.

Prior to entering the study, all patients signed an informed consent, after reading and understanding its content. The Ethical Committee of the University approval was obtained before the study began.

RESULTS

We evaluated a group of 71 subjects with obesity and type 2 diabetes with an average age of 60.14 years.

Of the whole study group, 29 (40.8%) were men and 42 (59.2%) were women.

The clinical and anthropometric characteristics are presented in first table.

Statistically significant differences were observed in the total caloric and cholesterol intake between men and women (the mean values being higher in men) (tab. II).

Regarding the average daily intake of each food group, statistically significant differences were found for alcohol, eggs, meat and derivatives, soups and sauces intake between sexes (higher mean values in men) (tab. III).

Only 60 subjects answered the questions about the frequency of meals per day and other habits, and we noticed that little more than half consumed three main meals a day, one third skipped breakfast and about a quarter had the habit of eating in front of the TV. Those who chose some unhealthy habits had a higher daily energy intake (tab. IV).

TABLE I

Clinical characteristics of participants by sex

	sex	N	Mean	Std. Deviation	Std. Error Mean	P sig.
Weight	men	29	106.690	16.8313	3.1255	**0.001**

TABLE IV

The main eating behaviors that resulted from the questionnaire

		Frequency(N)	Percent (%)	Energy (kcal)
3 daily meals	daily	33	55.0	1598
	often	16	26.7	1856
	rarely	11	18.3	1890
Skipping breakfast	yes	18	30%	1843
	no	42	70%	1667
High-energy meal after 9 p.m.	often	7	11.7	1934
	rarely	53	88.3	1692
Eating during night	yes	9	15.0	1969
	no	51	85.0	1676
Eating in front of the TV	yes	16	26.7	1861
	no	44	73.3	1669

As for the frequency of food consumption, we noticed that men consumed significantly more pork, bacon, sausages, liver pates, fries, eggs, vegetable soups, meat soups, alcohol, garlic, tomatoes ($p<0.005$), while women consumed significantly more margarine ($p <0.005$). Whole bread, cereals, pods, corn and dried fruit were consumed equally. Otherwise, the differences were not statistically significant (data not shown).

Most of the subjects consumed sunflower oil, but for cooking they preferred to use butter. Also, almost half of the subjects who usually consumed milk chose to consume whole milk (tab. V).

By correlating the frequency of food consumption with anthropometric indices, we found that the weight correlated positively with the consumption of hamburger ($r = 0.264$, $p = 0.026$), lamb ($r = 0.396$, $p = 0.001$), meat pie ($r = 0.260$, $p = 0.038$), biscuits ($r = 0.260$, $p = 0.029$), melons ($r = 0.333$, $p = 0.005$) and negatively with consumption of tofu, dairy desserts ($r = -0.241$, $p = 0.043$). WC was positively correlated with lamb consumption ($r = 0.375$, $p = 0.001$), melon ($r = 0.312$, $p = 0.008$) and negatively with consumption of dairy desserts ($r = -0.269$, $p = 0.023$). BP correlated negatively with avocado consumption ($r = -0.267$, $p = 0.024$).

TABLE V

Fats and milk intake by preference

Food		Percent	Food		Percent
Oil	sunflower	88.1	Cooking fat	sunflower oil	14.0
	olive oil	11.9		margarine	7.0
Visible meat fat	most	15.5		butter	55.8
	a part	19.7		solid margarine	4.7
	little	63.4		poly-unsaturated margarine	16.3
	none	1.4		lard	2.3
Milk daily	none	26.8	Milk type	fatty	25.8
	150ml	42.3		powdered	18.2
	300ml	22.5		whole	47.0
	450ml	5.6		semi skimmed	9.1

By correlating the frequency of food consumption with some biological parameters, cholesterol was found to correlate positively with consumption of fatty fish (r = 0.343, p = 0.004) and peanut butter (r = 0.239, p = 0.046). LDL-cholesterol correlated positively with the consumption of fatty fish (r = 0.278, p = 0.023) and negatively with the consumption of lentils (r = -243, p = 0.048). HDL-cholesterol correlated positively with consumption of black bread (r = 0.298, p = 0.016), peanut butter (r = 0.313, p = 0.011) and negatively with sausage consumption (r = -0.257, p = 0.039), liver pate (r = -0.282, p = 0.023). γGT correlated negatively with coffee consumption (r = -0.254, p = 0.034) and positively with consumption of fatty fish (r = 0.282, p = 0.018). Transaminases correlated positively with the consumption of wine (r = 0.252, p = 0.036), and negatively with coffee consumption (r = -0.290, p = 0.015).

To determine food patterns we used factorial analysis, and subsequently cluster analysis. The KMO value was 0.782, which allowed further analysis. An Eigen values >1.0 criterion was considered, which allowed the identification of 4 factors (food categories), representing 67.3% of the total variance of food intake. Factor loadings >0.3 was considered to have an increased contribution to each category (tab. VI). The first category explained 38.4% of the variance and was named *mixed foods*, characterized by increased intake of cereals and derivatives, fats/oils, fish and derivatives, fruits, meat and derivatives, milk and derivatives, potatoes, vegetables. The second category explained 11.4% of the variance and was named *traditional foods*, characterized by an increased intake of soups and sauces and an average intake of meat and derivatives, fruits and vegetables. The third category explained 9.3% of the variance and was named *protein foods*, characterized by increased intake of non-alcoholic beverages, eggs and moderate intake of meat and derivatives. The fourth category explained 8% of the variance and was named *sugars*, characterized by high intake of sugar, snacks and alcoholic beverages.

TABLE VI

Food categories derived from factor analysis based on factor loadings

Food groups + alcohol	Food categories			
	mixt foods	*traditional foods*	*protein foods*	*sugars*
Alcohol	.102	.194	.163	.817
Cereals and derivatives	.818	.038	.261	.074
Eggs	.241	.081	.619	.127

Based on the four food categories, a cluster analysis was subsequently performed, resulting three exclusive clusters representing three food patterns (traditional pattern – with 67.62% of the participants, prudent pattern – with 4.22% of the participants and Western-like pattern – with 28.16% of the participants) (tab. VIII, fig. 1).

The *traditional pattern* had a high correlation with traditional foods and moderated with the other food categories. The *prudent pattern* had high scores for mixed foods and low scores for sweets/snacks/alcohol. The *Western-like pattern* had a high positive association with sweets/snacks/alcohol and a negative association with traditional foods (tab. IX).

TABLE VIII

Cluster analysis based on food categories scores

HbA1c (%)	6.8%	6.7%	7.4%	0.134
Waist-to-hip ratio	0.99	0.97	1	0.187

DISCUSSION

Increasing the burden of chronic disease requires an alternative and complementary approach to the relationship between diet and the risk of these diseases.

We presented in this study the dietary

patterns identified in people with obesity, highlighting the significant differences in the frequency of food consumption by gender, certain dietary preferences and analyzing the possible association between food patterns and biological parameters. The interpretation of the questionnaires revealed that the daily intake of macronutrients was consistent with the intervals recommended by the guidelines (20).

For those who had a high-energy meal after 9 p.m., those who had the habit of eating in front of TV or during night, those who skipped breakfast and those who did not have 3 main meals per day, the average energy intake was higher. Only half of the participants had regularly 3 main meals per day. In a study that used three 24-hour questionnaires applied over a year to 499 people, following the frequency and timing of the meals, breakfast and meals in the city, it was found that the habit of eating several times a day was associated with the lowest risk of obesity (21).

Four categories of foods were identified in our study participants. The first (mixed foods) includes cereals and derivatives, fats/oils, fish and derivatives, fruits, meat and derivatives, milk and derivatives, potatoes, vegetables. The second (traditional foods) includes an increased intake of soups and sauces and the average intake of meat and derivatives, fruits and vegetables. The third category (protein foods), characterized by high intake of eggs, non-alcoholic beverages and moderate intake of meat and derivatives. The fourth category (sugars) includes sugar, snacks and alcoholic beverages. Subsequently, we continued the analysis of these categories using cluster analysis, which allowed the subjects to be divided into three distinct food patterns based on the consumption of foods from the four categories derived originally. *The traditional pattern* was adopted by the largest group, more than half of the participants (67.62%), and was characterized by the high intake of soups and sauces, and medium intake of foods from the prudent pattern. The *prudent pattern* was adopted by a low percentage of subjects (4.22%) and was characterized by a high intake of cereals, fats/oils, fish, meat, potatoes, vegetables, a medium intake of eggs and nonalcoholic drinks and a low intake of sugar, snacks, alcohol. The *Western-like pattern* was adopted by 28.16%, including an increased intake of sweets/ snacks/alcohol and low intake of soups, sauces. Interestingly, our study showed that even if the patients following a prudent pattern had the highest energy intake, they also had the best cardio-metabolic parameters, whereas the patients following a Western-like pattern had the worst metabolic parameters (WC, HbA1c).

A study conducted in Taiwan on middle-aged and elderly adults found that the food pattern rich in animal proteins, saturated fats, sweets, sodium and food additives was positively associated with C reactive protein (22). However, we did not find the same results. A cross-sectional study of 138 overweight and obese Egyptian women showed that the most common unhealthy eating habits associated with the risk of obesity were skipping breakfast, eating in front of the TV, frequent intake of "snacks" and sweets and low portions of fruit and vegetables (23). Regarding gender differences, although not statistically significant, it was noted that most men adopted the traditional diet more than women (75.9% vs. 61.9%), for the other patterns the percentages are similar.

We found that the frequency of red meat consumption (lamb in our study) was positively associated with anthropometric indices (hence associated with obesity and central obesity) and negatively with HDL-cholesterol. The evidence from The National Health and Nutrition Examination Survey

(NHANES) highlighted the importance of investigating the effects of red meat consumption on the health status (including obesity and central obesity) (24, 25).

Fatty fish consumption was positively associated with serum levels of cholesterol, LDL-cholesterol and γGT. It would be interesting to further investigate cooking methods of fish in Romania (especially frying), which could possibly explain this unusual finding. Black bread and peanut butter were positively associated with HDL-cholesterol, as expected.

We found an inverse association between coffee intake and serum transaminases and γGT levels. Coffee intake could have potential benefits (inhibit inflammation, reduce cardiovascular disease, reduce induction of the cytochrome P450 system) (26, 27) that could be related to some antioxidants found in coffee. These compounds may inhibit the increase in serum transaminases and γGT levels. Other studies also found this inverse association (28).

The study has several limitations: the small number of subjects, the lack of comparison with normal weight individuals and people without diabetes, the observational nature of the study. Thus, we should consider a further study on a larger sample.

CONCLUSIONS

In this study we identified three major food patterns in subjects with obesity, that could help us implement behavior and lifestyle changes in these individuals.

NEWS

INCREASED INTEGRATION OF EXTRACELLULAR DNA IN THE ENVIRONMENTAL METAGENOME IN THE PRESENCE OF MUTAGENS LIKE BROMOACETIC ACID

A study by Mantilla-Calderon D *et al.*demonstrated that bromoacetic acid can increase transformation rates in microorganisms. Bromoacetic acid is a drinking water disinfection byproduct. Natural transformation allows for the uptake and integration of foreign DNA, which is a form of horizontal transfer of genes. This can be responsible for the acquisition of virulence and antibiotic resistance. The model microorganism used in the study was *Acinetobacter baylyi* ADP1. The transformation rate in this study was dependent on concentration of bromoacetic acid and its ability to cause DNA damage. Thus, transcription of recA gene was enhanced by 20 to 40%. This, in turn, facilitates the integration of extracellular DNA within the acceptor bacterial cell during DNA repair. (Mantilla-Calderon D, Plewa MJ, Michoud G, Fodelianakis S, Daffonchio D, Hong P. Water disinfection byproducts increase natural transformation rates of environmental DNA in *Acinetobacter baylyi* ADP1. *Environ Sci Technol.* 2019 May 3. doi: 10.1021/acs.est.9b00692.)

ASSOCIATED RISK FACTORS FOR PANCREATIC CANCER: POTENTIAL TARGETS IN EARLY DETECTION STRATEGIES

ASSOCIATED RISK FACTORS FOR PANCREATIC CANCER: POTENTIAL TARGETS IN EARLY DETECTION STRATEGIES (Abstract) : The common risk factors for pancreatic cancer (PC) are smoking, high alcohol consumption, obesity, family history of PC and dietary factors. Chronic pancreatitis facilitates the progression to cancer, resulting in the occurrence of precancerous lesions. Genetic factors variation or mutation contribute to increase risk of PC**.** The biomarker combination CA19-9 (Carbohydrate antigen 19-9 , also known as sialyl-Lewis) along with MUC5AC (Mucin 5AC - this gene has been linked to mucus hypersecretion**)** is also suggestive for PC diagnosis. Transabdominal ultrasound, contrast enhanced computed tomography or magnetic resonance imaging are used to detect PC, but positron emission tomography with fluoro-D-glucose is clearly superior in early detection of small tumors. **Keywords**: PANCREATIC CANCER, RISK FACTORS, EARLY DETECTION.

Pancreatic cancer (PC) is an aggressive and invariably deadly disease without any improvements in patient outcome over the last 2 decades. The estimated number of deaths in 2013 was around 39,000, making PC the fourth leading cause of cancer deaths in the USA, with over 45,220 new cases diagnosed every year (1).

EPIDEMIOLOGY

The worldwide incidence of pancreatic ductal adenocarcinoma (PDAC) is 6-12/100,000/year (2) and it is seldom diagnosed before 55 years old. PDAC can be defined as a disease of elderly populations with the highest incidence in people older than 70 (3).The incidence of PDAC varies across regions and populations, possibly because of the environment and/or the exposure to certain risk factors.

RISK FACTORS FOR PC

The etiology of PC represents the subject of numerous meta-analyses and pooled analyses in order to establish several risk factors. The most common risk factor is

tobacco smoking, followed by obesity, high alcohol consumption, history of pancreatitis and diabetes, family history of PC and possibly selected dietary factors (4).

Acute pancreatitis (AP), a sterile inflammation initiates from acinar cell injury following a series of impairment of pancreatic enzymes activation processes, increased inflammatory responses and ultimately cell death with the complication of multiple organ failure (5, 6). The most common causes of pancreatitis include alcohol, gallstones, toxins, hyperlipidemia, and trauma, with a small number of idiopathic cases. Traditionally AP is self-limited with complete resolution of function after the acute event, but sometimes there may be stricture formation, leading to pancreatic flow obstruction and recurrent AP (RAP). Recurrent episode of AP would progress to chronic pancreatitis (CP), which is a well-defined risk factor for PC (1). There are three stages of CP development: stage one (the pre-pancreatitis phase), associated with risk factors for this transition, like alcohol consumption and tobacco smoking (6). Then, stage two (AP form) with release of inflammatory cytokines which, in the severe forms, it could activate macrophage dependent stellate cells, which finally could lead to fibrosis. The third stage is represented by the progression to CP driven by the factors that modulate immune responses (7).

In one recent study of 731 prospectively enrolled patients after a primary episode of AP, the risk of future development of PDAC was 0.7%, after median of 55 months of follow-up. The study also showed that the risk of PC was 9 times higher in patients who developed CP (8). Another study among 790 patients with histologically confirmed PC, 114 (14.4%) had a history of pancreatitis (AP within 2 years of PC diagnosis in 69 [8.7%], remote history of AP in 28[3.5%], CP in 4[0.5%], and unknown duration of pancreatitis in 13[1.6%]. After controlling for sex, age, body mass index, smoking, alcohol history, and diabetic status at diagnosis, patients with a remote history of AP were diagnosed on average 4.7 years earlier with PC compared with PC patients without history of AP (9).

CP is a refractory disorder characteristic of progressive inflammation and fibrosis with irreversible damage to both exocrine and endocrine function of the pancreas. Acinar cell atrophy, pancreatic fibrosis, leukocytes infiltration, fatty replacement and blocked ducts represent the typical histopathologic features of CP (10). Both CP and PDAC include massive immune cell infiltration and intensive fibrosis (1).

A meta-analysis among patients with CP has shown a relative risk of 13.3% for developing PC (2). Chronic inflammation associated with CP facilitates the progression to cancer, resulting in the occurrence of three types of precancerous lesions: pancreatic intraepithelial neoplasia (PanINs), intraductal papillary mucinous neoplasms (IPMN) and mucinous cystic neoplasms (MCN). Subsequent evolution of these precursor lesions into PDAC ultimately involves a number of various molecular changes (11). Despite the strong link between CP and PC, less than 5% of patients with CP go on to develop the disease (2).

Among the non-modifiable risk factors are diabetes mellitus, age, genetic factors and gender. PC is more common in males than in females, possibly due to lifestyle (higher alcohol and tobacco consumption) (12).

Genetic factors contribute to increase risk of PC and the most important are genetic variation or mutation of BRCA1 (Breast cancer type 1 susceptibility protein), BRCA2, PALB2 (Partner and localizer of BRCA2, also known as PALB2), ATM (ataxia telangiectasia mutated), CDKN2A (cyclin-dependent kinase Inhibitor 2A) , APC (Adenomatous polyposis coli), MLH1 (MutL homolog 1, colon cancer, nonpolyposis type 2 E. coli), MSH2 (DNA mismatch repair protein Msh2), MSH6, PMS2(Mismatch repair endonuclease), PRSS1 (Mutations of Human Cationic Trypsinogen) and STK11 (Serine/ threonine kinase 11). 5-17% of families with familial PC have been identified with Germ-line BRCA2 gene mutations, the highest proportion of known causes of inherited PC. Also, familial cancer syndromes (hereditary non-polyposis colon cancer, Peutz-Jeghers syndrome, hereditary breast and ovarian cancer syndrome, familial adenomatous polyposis and Li-Fraumeni syndrome) found to be associated with PC (13).

LABORATORY INVESTIGATIONS

Serum bilirubin levels are greater than 10 mg/dL in CP, with a peak followed by a fall as inflammation decreases (14). In PDAC, bilirubin progressively increases till biliary decompression is done (15).When serum bilirubin >5.8 mg/dL, MPD> 11.5 mm, CBD>14.5 and CA 19-9 >127 UI/mL, the sensitivity for suspecting malignancy is 100% (16). Ca 19-9, the gold standard PDAC biomarker, is the single most important predictive biomarker of malignancy in mass forming CP with a sensitivity and specificity of 77% and 86% (17). However, the value can be elevated in obstructive jaundice, cholangitis, cirrhosis and CP in absence of malignancy (18). A proinflammatory marker of CXC chemokine family, interleukin 8, is found to be commonly expressed in PDAC (55.6%) and it can predict the prognosis (19).

Methylated biomarkers such as KRAS are found to be 95% specific and 75% sensitive for PDAC in comparison with normal controls and CP. A metabolic signature to distinguish PDAC from CP, with a diagnostic accuracy of 90%, contains CA 19-9 along with certain metabolites such as proline, 2 sphingomyelin, phosphatidylcholine, pyruvate, ceramide, histidine, sphingosine-1-phosphate and isocitrate, with an 85% sensitivity and 94,9% specificity (20).

The biomarker combination which is found to be very promising is CA 19-9 along with MUC5AC, a mucin family member produced by both well differentiated and poorly differentiated PDAC (17). MUC5AC is undetectable in normal pancreas, islet cell tumors and CP (21). Its levels are affected by elevated bilirubin levels. Serum levels can be measured by enzyme-linked immunosorbent assay, whereas tissue levels can be measured by immunohistochemistry (17).

A monoclonal antibody with high specificity for MUC1 **(**Mucin 1, cell surface associated) is PAM4, found to be expressed in PDAC as compared to normal pancreatic tissue and pancreatitis. It has a better sensitivity and specificity than CA 19-9 (22).

A recent study made by Lukasiewicz-Zajac *et al.* showed that matrix metaloproteinase-2 (MMP-2) and its tissue inhibitor (TIMP-2) are highly useful as potential biomarkers in the diagnosis of PC. MMP-2 is a proteolytic enzyme responsible for the degradation of the basal membrane and extracellular matrix. Imbalance between MMP-2 and TIMP-2 have a significant role

in invasion, migration, metastasis of tumoral cell and neoangiogenesis (23).

The study of Zhai *et al.* proved, by immunohistochemical methods, that the expression of MMP-2 was higher in PC tissue, fact that was positively correlated with higher CA 19-9 serum levels, with poor histological grade, advanced stage, perineural invasion, lymph node and distant metastasis (24).

Another study revealed a new combination of CA 19-9, thrombospondin-2 (THBS2) and circulating cell-free DNA (cfDNA) as a composite liquid biomarker for the diagnosis of early-stage PDAC. This panel showed a 92% sensitivity in discriminating PDAC from CP or IPMN (25).

IMAGING

Abdominal X-ray, transabdominal ultrasound (USG), contrast enhanced computed tomography (CECT) or magnetic resonance imaging (MRI) can be used to detect morphological changes in the pancreas, ductal findings, metastatic lesions, ascites, lymphadenopathy and vascular involvement (26, 27).

Radiologically, a malignancy in CP may appear like a lesion in diffuse CP or a mass forming focal CP (28).

USG can be useful especially when the patient has liver metastatic disease and/or ascites. In those cases, an USG-guided biopsy or fluid cytology can establish the diagnosis. A contrast-enhanced USG in arterial and venous phases is useful only when the malignancy is advanced with vascular involvement (29).

A triple-phase pancreas protocol CECT scan represents one of the main investigations. Frequently, PDAC is seen as a gradual, progressive hypo enhancing lesion with a delayed peak in the portal phase without washout and pancreatic parenchymal atrophy/PDAC, often localized in the head of pancreas, is associated with dilated CBD and MPD (double duct sign), with an abrupt cutoff at the mass. Vascular sheathing at origin of celiac artery and superior mesenteric artery by a hypodense mass is suggestive for malignancy (26). However, 23% of small PC (<20 mm) cannot be detected (30). Another causes of this low sensitivity may be represented by some pathological characteristics of the tumor such as lower tumor cellularity, less prominent tumor necrosis and more frequent intratumorally islet cells and acinar tissues (31).

MRI has a stronger contrast enhancement and a superior ability to detect PDAC when compared with CT (32). Diffusion-weighted MRI (DWI) can help detect pancreatic neoplasms with extracellular fibrosis or extremely dense cellularity, but it cannot definitively characterize solid lesions as neoplastic or inflammatory (33).

Positron emission tomography with 2-deoxy - 2[fluorine-18] fluoro-D-glucose (FDG-PET) is superior to MRI and CT, with 89% sensitivity and 88% specificity, being able to detect PC < 20 mm. For that matter, it is used for cancer staging and revealing recurrent lesions (34).

Endoscopic ultrasonography (EUS) become the most sensitive examination for PDAC in patients with high-risk factors for PDAC or with manifestations suggesting PC (35).

The conventional B-mode EUS imaging was complemented by ultrasound contrast agents (UCAs), which allows the evaluation of vascular structures. Contrast-enhanced high mechanical index (CEHMI) EUS and contrast-enhanced low mechanical index (CELMI) are helpful for detecting

macro vessels, respectively capillary vascularization patterns inside the area of interest. Endoscopic son elastography (ESE) tests the hardness of tissue and benign tissue is more pliant compared to a malignant tumor. A recent study made by Finn-Jorn *et al*. showed that CEHMI-EUS can detect PDAC and differentiate it from CP more effectively than CT, conventional EUS, ESE and CELMI-EUS (36).

ERCP has a low sensitivity for diagnosing PC, being considered to be inadequate for examination. Besides, post-ERCP pancreatitis is a very unpleasant adverse event (37). Serial pancreatic juice aspiration cytologic examination (SPACE) was recently developed. It proved to have a high sensitivity and specificity even for pancreatic carcinoma in situ or small lesions (38).

CONCLUSIONS

Pancreatic cancer is a major health problem, being one of the most aggressive forms of cancer.

Acute and chronic inflammation associated with CP facilitates the progression to cancer, resulting in the occurrence of precancerous lesions.

CA 19-9 with MUC5AC combination may become an ideal investigation in PC detection strategies (39).

FDG-PET is superior to MRI and CT, with high sensitivity and specificity, being able to detect PC < 2 cm.

POLYMERIC NANOPARTICLES FOR ORAL DELIVERY OF INSULIN

Biomacromolecules have transformed our capacity to effectively treat diseases; however, their rapid degradation and poor absorption in the gastrointestinal (GI) tract generally limit their administration to parenteral routes. An oral biologic delivery system must aid in both localization and permeation to achieve systemic drug uptake. Inspired by the leopard tortoise's ability to passively reorient, we developed an ingestible self-orienting millimeter-scale applicator (SOMA) that autonomously positions itself to engage with GI tissue. Gastrointestinal responsive polymeric nanospheres (NPs) based on hydroxypropyl methylcellulose phthalate (HPMCP) were prepared using spontaneous emulsification solvent diffusion method for improved oral administration of insulin. The NPs were prepared under optimized conditions have an encapsulation efficiency of 90% and a particle size of about 200 nm. In vitro drug release experiments demonstrated that the NPs exhibited a gradient release profile of loaded drug when the pH value gradually increased from 3.0 to 7.4. Enzyme resistance experiments showed that under simulated gastrointestinal conditions, the NPs protected more than 60% of the drug from being degraded by trypsin. The oral hypoglycemic experiments revealed that insulin-loaded NPs could significantly reduce blood glucose levels in diabetic rats with a relative bioavailability of 8.6%. *Ex vivo* imaging investigation of rat tissues showed that the drug-loaded NPs could promote the absorption of insulin in the ileum and colon. The work described here suggests that the gastrointestinal responsive polymeric NPs may be promising candidates for improving gastrointestinal tract delivery of hydrophilic biomacromolecules. Accordingly, the results indicated that HPMCP NPs with gastrointestinal stimuli responsiveness could be a promising candidate for oral insulin delivery (Y. Fang, Q Wang, Lin X, *et al.* Gastrointestinal responsive polymeric nanoparticles for oral delivery of insulin: optimized preparation, characterization and *in vivo* evaluation. *J Pahrm Sci* 2019; 108(9): 2994-3002).

TRATAMENTUL MEDICAMENTOS AL POLINEUROPATIEI DIABETICE PERIFERICE

DRUG TREATMENT OF DIABETIC PERIPHERIC POLYNEUROPATHY (Abstract): Neuropathy is one of the many complications of diabetes mellitus, along with micro- and macroangiopathy. Chronic sensorimotor distal symmetric polyneuropathy is the most common form between neuropathies; more than 30% of the diabetic patients are affected by this complication. Treatment is based on three cornerstones: 1) multifactorial intervention aimed at normoglycemia; 2) drugs that target pathogenic mechanisms and 3) symptomatic treatment. Among pathogenic treatments, alpha-lipoic acid and benfotiamine are available in several countries. Neuropathic pain, which affects 8–26% of diabetic patients, exerts a substantial impact on the quality of life. Among the centrally acting analgesic drugs, tricyclic antidepressants, carbamazepine, gabapentin and opioids have been mainly used to treat neuropathic pain. More recently, significant pain relief has been reported using agents such as duloxetine, a dual selective serotonin noradrenaline reuptake inhibitor, and pregabalin, an anticonvulsant, a specific modulator of the $\alpha_2\delta$ subunit of the voltage-dependent calcium channels. Until now, at least 50 new molecular entities have reached clinical stage of development. Strategies that may show promise over existing treatments include topical therapies, analgesic combinations and, in future, gene-related therapies. **Key words**: DIABETIC POLYNEUROPATHY, NEURO--PATHIC PAIN, DULOXETINE, PREGABALIN

GOOD NEWS: COFFEE IN LIVER DISEASE

GOOD NEWS: COFFEE IN LIVER DISEASE (Abstract): Each day more than 2.25 billion cups of coffee are consumed, requiring over 7 million tons of coffee beans. Roasted coffee brew contains more than 1,000 bioactive substances that provide substantial human health benefits. The micronutrient content of coffee depends on chemical transformation, type of bean, degree of roast, preparation method, while bioavailability is influenced by the individual genotype and gut microbiota. Coffee has proven bioactivities including antiproliferative effect, neuroprotective function, antioxidant activities, antidiabetic effect, and hypolipidemic effects. Coffee intake is associated with a reduced risk of hepatocellular carcinoma, liver-associated enzyme elevations, hospitalizations and mortality from cirrhosis and with a reduced replication capacity of the hepatitis C virus, thus improving the response to antiviral therapy. "A coffee prescription" can be a practical prophylactic and therapeutic approach. Randomized control trials are required to standardize the type, dose and method of preparation. **Keywords**: COFFEE, LIVER, ANTI-FIBROTIC, BIOACTIVE.

Coffee, known as "the wine of Arabia", is the second world's most traded commodity after petroleum and its rich history dates back more than one thousand years. The coffee plant first grew wild in the cloud forests in Kaffa, in the ancient Abyssinia (Ethiopia). According to "One Thousand and One Nights", a collection of Middle Eastern and South Asian folk tales published during the Islamic Golden Age, the brewing of coffee beans began after a goat herder named Kaldi noticed that his goats became energetic after eating a certain type of wild red berries. The first reliable evidence of coffee drinking is from the early 15th century, in the Sufi monasteries of Yemen (1). Through trade, the cultivation of coffee plant spread to Arabian Peninsula and later, to India, Europe and Latin America. Nowadays, Brazil is the world's largest coffee producer and exporter, followed by Vietnam and Colombia. Coffee, once thought to be a devilish drink, forged a social revolution all over the world, including among the great composers like Bach, who deliberately composed the "Coffee Cantata" (2).

Roasted coffee brew contains more than 1,000 bioactive compounds that provide substantial human health benefits. Some of them are represented by mineral ingredi-

ents such as Ca, K, Fe, P, Ni, Mg and Cr, polyphenols, caffeine, melanoidins, lipids and carbohydrates (3). The final coffee micronutrient content depends on chemical transformation, type of bean, degree of roast, preparation method, while bioavailability is influenced by the individual genotype and gut microbiota (4).

Coffee has proven bioactivities, including antiproliferative effect against some cancer cell lines, neuroprotective function by inhibiting acetylcholinesterase, playing a potential role in the treatment of Alzheimer's disease, antioxidant activities against ischemia-reperfusion injury, antidiabetic effect, each cup of coffee leading to a 7% reduction in the risk of type 2 diabetes, hypolipidemic effects, leading to weight reduction in experimental mice and antimicrobial activities, including anti-HIV activity (5).

Coffee consumption is consistently associated for about 20 years with a decreased risk of liver disease, but the first a histopathological evidence of a reduction of fibrosis occurred several years ago. Coffee intake is associated with a decreased risk of hepatocellular carcinoma (HCC), liver-associated enzyme elevations, hospitalizations and mortality from cirrhosis, and with a reduction in the replication capacity of hepatitis C virus, thus improving the response to antiviral therapy (6, 7).

Bioactive compounds of coffee with potential benefits in liver disease

The most representative and studied compounds are caffeine, chlorogenic acid, diterpenes and trigonelline (3). Caffeine is a purine methylxanthine alkaloid found in many products like *Caffea arabica*, *Caffea canephora* (*Robusta*), green tea, mate tea, chocolate, cola and energy drinks.

Experimental data revealed that caffeine has antioxidant activity and that its administration can block the elevation of TGF-β, a profibrogenic cytokine highly expressed in deregulation of physiological tissue remodeling processes (8,9). Other experimental studies suggested that caffeine induces the expression of uridine diphosphate-glucuronyltransferases in liver, the most important proteins involved in phase II drug metabolism (10,11).

Chlorogenic acid, a phenolic compound isolated from green coffee beans, is supposed to play an important anti-fibrotic role by blocking the miR-21-regulated TGF-β1/Smad7 signaling pathway (12).

The fat soluble diterpenes cafestol and kahweol are typically removed from coffee by paper filters. Cafestol can be found in both *robusta* and *arabica* beans while kahweol can be found only in the unfiltered major strain arabica (13). These compounds are believed to protect against oxidative stress by stimulating the NF-E2-related factor-2 (Nrf2)-ARE (antioxidant responsive element) pathway. Activation of Nrf2-ARE pathway ameliorates alcoholic liver disease, protects HCC cells and viral hepatitis-infected cells against oxidative injury and inhibits the c-Jun N-terminal kinases (JNK) pathway involved in the pathogenesis of nonalcoholic fatty liver disease (14).

Trigonelline, a pyridine alkaloid with antioxidant properties found in large amounts in *Caffea arabica*, prevents hepatic lipid accumulation in experimental models of nonalcoholic fatty liver disease by restoring hepatic autophagy (15). Quercetin is another coffee compound from the flavonoid group of polyphenols that has been found to have antioxidant properties due to intracellular free radical scavenging capacities, leading to improvement of liver inflammation and fibrosis (16).

Impact of coffee on liver enzymes

Inverse associations of coffee with liver enzyme gamma-glutamyltransferase (GGT) were first mentioned in "The Tromso heart study" published by Arnesen in 1986 (17). Many other population-based studies published in the last years noticed a dose-dependent decrease in aspartate aminotransferase (AST), alanine aminotransferase (ALT) and alkaline phosphatase (ALP) in individuals drinking > 3 cups of coffee daily (6). The outcome was more obvious in patients with diseases or conditions that were likely to cause liver injury (obesity, alcohol consumption of more than two alcoholic beverages daily, transferrin saturation >50%, impaired glucose tolerance and viral hepatitis) (6, 18). The enzyme-lowering effect was less marked in women aged over 50 years (6).

Nonalcoholic fatty liver disease

Current epidemiological and clinical evidence suggests that regular caffeine consumption, defined as the ingestion of caffeine only from regular coffee, excluding espresso, tea and cola, plays a protective role in the development of nonalcoholic fatty liver disease by decreasing the activity of connective tissue growth factor (CTGF), a central promoter of liver fibrosis, and by modifying effects on the metabolic syndrome (decrease in proinflammatory cytokines, change in adipose tissue gene expression, decrease of liver fat and collagen deposition) (6,18-20).

Chronic hepatitis B and C

Coffee intake is associated with lower rates of liver disease progression in patients with chronic hepatitis C (21). *In vitro* studies demonstrated that caffeine was able to inhibit viral replication in a dose-dependent manner at noncytotoxic concentrations (18,22). High coffee intake (more than 3 cups a day) in naive patients treated with peg-interferon and ribavirin resulted in increased tolerability of treatment (50.4-60.6%) and improvement of sustained virological response (SVR).

Reduction of side effects was also demonstrated in HIV-HCV-coinfected patients treated with peg-interferon and ribavirin (23).

Although *in vitro* studies have shown a quantitative reduction of HBsAg levels and a low level of HBV DNA in the HEPG2 cell lines, clinical evidence has not shown that coffee consumption could reduce liver fibrosis (18).

Liver cirrhosis

Coffee consumption was associated with lower risk of mortality from chronic liver disease (CLD) in a dose dependent manner (1 cup of coffee daily was associated with a 15% reduction in the risk of death from CLD while 4 cups daily resulted in a 71% reduction in risk of death from CLD). The same association was not statistically significant when black tea, green tea and other non-alcoholic caffeinated drinks were consumed.

In experimental rat models, coffee administration suppressed the activation of profibrogenic cytokines including TGF-β, PDGF and CTGF and protected the depletion of glutathione, superoxide dismutase and catalase in liver tissue, defending stellate cells from ROS (reactive oxygen species)-induced necrosis (19).

Hepatocellular carcinoma

Coffee consumption reduces the risk of HCC, irrespective of the etiology of liver disease, by 40% in coffee drinkers versus

non-drinkers, directly proportional with the amount and duration of coffee consumption.

Both *in vitro* and *in vivo* studies have demonstrated that chlorogenic acid has anticarcinogenic effects. Recent evidence suggests that chlorogenic acid improves the effects of Regorafenib in human hepatocellular carcinoma cells (24).

CONCLUSIONS

Our review suggests that no other available antifibrotic agent for liver disease is cheaper, more accessible irrespective of the socioeconomic status, pleasant to consume and effective regardless of the underlying liver disease than coffee. Randomized control trials are needed to standardize the coffee types, dose and method of preparation.

NEWS

HYPERHOMOCYSTEINEMIA IS AN INDEPENDENT RISK FACTOR FOR INTRACRANIAL ATHEROSCLEROTIC STENOSIS

Stroke has become one of the main causes of disability and death among the population. Intracranial atherosclerotic stenosis (ICAS) is the most common cause of stroke. It is essential to identify, prevent and treatment he modifiable risk factors of ICAS. Hyperhomocysteinemia (HHcy) is considered a risk factor for cardiovascular disease and atherosclerosis. In addition, the exiting data in literature on the existing literature on the relationship between serum homocysteine level and stroke is still controversial. A new study published in *AGING* examines the association of homocysteine concentration with ICAS. According to statistical and processing data, HHcy could be an important marker of vascular injury and a potential target for the prevention of vascular injury, especially for intracranial artery. Therefore, the research group´s conclusion was that increased homocysteine may be an independent risk factor for intracranial atherosclerotic stenosis (Ying Liu,Jing-Hui Song, Xiao-He Hou et al. Elevated homocysteine as an independent risk for intracranial atherosclerotic stenosis. *AGING* 2019; 11(11)).

WHICH PATIENTS WITH SUSPECTED MYOCARDIAL ISCHEMIA AND BUNDLE BRANCH BLOCK SHOULD RECEIVE EMERGENCY REPERFUSION THERAPY ?

WHICH PATIENTS WITH SUSPECTED MYOCARDIAL ISCHEMIA AND BUNDLE BRANCH BLOCK SHOULD RECEIVE EMERGENCY REPERFUSION THERAPY ? (Abstract): The electrocardiogram is one of the first test directing reperfusion therapy for patients with acute myocardial infarction, depending on the presence or absence of ST-segment elevation. The presence of left or right bundle branch block on an electrocardiogram is frequently encountered in our clinical practice and their hemodynamic implications are increasingly being studied. However, the presence of left bundle block is usually associated with a more reserved prognosis compared to normal intraventricular conduction. In the same time, the presence of right bundle branch block is often considered benign in the absence of a cardiac pathology. Also, left bundle branch block has historically prevented accurate recognition of acute myocardial infarction. This may lead to a poor allocation of reperfusion therapy and secondary to a suboptimal patient outcome. Over the past 20 years, the management guidelines for these patients have shifted from one extreme to the other, considering the limited knowledge on this topic. In this context, the new European Society of Cardiology guideline recommends for patients with persistent ischemic symptoms and right bundle-branch block, a primary percutaneous coronary intervention strategy, but the level of evidence is not high. Considering that new-onset right bundle branch block may indicate the proximal occlusion of the left anterior descendent artery and large infarction, which may cause severe heart failure, malignant arrhythmias, complete atrioventricular block, an emergency reperfusion therapy may prevent all these. This is probably the reason why the current reperfusion therapy has changed the overall incidence and significance of right bundle branch block in acute myocardial infarction. In this clinical and epidemiological context, we consider justified to reanalyze and review the significance of left and right bundle branch block in the reperfusion therapy era. **Keywords:** BUNDLE BRANCH BLOCK, ACUTE MYOCARDIAL INFACTION, CORONARY ARTERY DISEASE, MORTALITY, ELECTROCARDIOGRAM.

The electrocardiogram (ECG) is an integral part of the diagnostic workup of patients with suspected myocardial infarction and should be acquired and interpreted promptly (i.e. target within 10 min) after first medical contact (1, 2). Patients with

acute myocardial ischemia have often dynamic changes in ECG waveform and serial ECG acquisition can provide critical information, especially if the ECG at initial presentation is non-diagnostic. Sometimes, patients may have other ECG signs that indicate acute myocardial ischemia, such as: intraventricular bundle branch block, cardiac arrhythmias, atrioventricular conduction delays or loss of precordial R wave amplitude, a less specific modification. However, in some cases like, acute pericarditis, left ventricular hypertrophy, left bundle branch block (LBBB), Brugada syndrome or early repolarization patterns, the ECG by itself is insufficient to diagnose acute myocardial ischemia or infarction, because in these conditions ST deviation may also be observed (3). Ischemic symptoms and presumed new left or right bundle branch block (RBBB) are associated with an adverse prognosis (4).

Left bundle branch block is traditionally regarded as the equivalent of an acute myocardial infarction with ST segment elevation (STEMI), but also it can be a marker of an ischemic or non-ischemic disease progression, affecting not only the cardiac conduction system but also the myocardium. The presence of marked ST-segment abnormalities may indicate an acute myocardial infarction, even if in the presence of LBBB, the ECG diagnosis of acute myocardial infarction (AMI) is difficult. Complex algorithms have been offered to assist the diagnosis, but they do not provide diagnostic certainty (5, 6). The presence of concordant ST-segment elevation $\geq$ 1 mm (i.e. in leads with positive QRS deflections) in patients with LBBB appears to be one of the best indicators of ongoing MI with an occluded infarct artery (7). Regardless the moment of occurrence of the LBBB, patients with a clinical suspicion of ongoing myocardial ischaemia and LBBB should be managed in a similar way as STEMI patients. It is also important to mention that the presence of a (presumed) new LBBB does not predict an AMI per se (4, 8).

Patients with myocardial infarction and RBBB have a poor prognosis (9,10) and it may be difficult to detect transmural ischemia in these patients. In this cases, new or presumed new ST-segment elevation $\geq$ 1 mm, or ST-segment or T wave abnormalities (excluding leads V1-V4), may indicate acute myocardial ischemia. New, or presumed new, RBBB without associated ST-segment or T wave changes is associated with thrombolysis in myocardial infarction (TIMI) 0-2 flow in as many as 66% of patients (compared with > 90% in those with ST-segment or T wave changes) (11). Considering that the blood supply of the right bundle-branch is mainly provided by left anterior descending artery (LAD) or the proximal septal perforator branch separated from LAD, new-onset RBBB may indicate the proximal occlusion of the LAD and large infarction. This can lead to severe heart failure, malignant arrhythmias, complete AV block and also a high mortality. But reperfusion therapy may prevent the appearance or limit the duration of bundle branch block, confirmed by studies that have reported the relationship between the reversibility of conduction disturbances and coronary reperfusion (12).

Given the poor prognosis of AMI patients with RBBB and the difficulty of determining the transmurality of an infarct in the setting of RBBB (13), the new European Society of Cardiology guideline suggests a primary percutaneous coronary intervention strategy when persistent ischemic symptoms occur in patients with

right bundle-branch block, but the level of evidence is not high (4).

In this context, the aim of our study was to assess the current data regarding which patients with suspected myocardial ischemia and bundle branch block should receive emergency reperfusion therapy.

LEFT BUNDLE BRANCH BLOCK

Patients with left bundle branch block and suspected acute coronary syndrome represent a diagnostic and therapeutic challenge for the clinician. For over 60 years, clinicians recognized the challenge of diagnosing acute myocardial infarction in the presence of the left bundle branch block (14). Since left ventricular activation in LBBB is delayed and initial activation of the interventricular septum is performed from right to left (contrary to the normal situation), Q waves suggestive of acute myocardial infarction are missing. Also, the secondary modifications of ST segment and T wave occurring in LBBB do not allow the recognition of signs of myocardial ischemia (15, 16). The electrocardiographic diagnosis of acute myocardial infarction is therefore difficult for these patients due to the masking of typical electrocardiographic changes (17).

Patients with acute ischemic symptoms and LBBB pose a unique diagnostic challenge, as it is frequently difficult to determine quickly whether the LBBB is new or old. Primary percutaneous intervention (PCI) is, according to the currently guidelines, the preferred method of reperfusion (4), but data regarding patients with new LBBB are limited. Even if these patients are less likely to have an acute culprit lesion at cardiac catheterization, they represent a high-risk population (18).

There is still an ambiguity regarding the management of patients with ischemic symptoms and new or presumed new LBBB. On the one hand, if these patients do not benefit from angiographic evaluation in an emergency, this will likely reduce the incidence of false activation of the catheterization laboratory and inappropriate fibrinolytic therapy. On the other hand, with holding appropriate reperfusion therapy in patients with a true coronary artery occlusion or acute coronary syndrome has the potential to increase morbidity and mortality (18).

Since the optimal use of myocardial reperfusion strategies is based on the rapid diagnosis of acute myocardial infarction, for most patients with angina, the electrocardiogram is an important element for assessing the cause of chest pain and for selecting the appropriate therapeutic management.

In the last decades, various electrocardiographic criteria have been proposed for the diagnosis of acute myocardial infarction in the presence of left bundle branch block (19,20). Of these, the Sgarbossa criteria are the most used (6,14). Sgarbossa *et al*. evaluated the role of the electrocardiogram in the diagnosis of acute myocardial infarction in patients with left bundle branch block and AMI documented based on the increase of myocardial cytolysis enzymes.

Three criteria are included in Sgarbossa's criteria (6):

- ST elevation ≥ 1 mm in a lead with a positive QRS complex (i.e. concordance) 5 points;
- concordant ST depression ≥1 mm in lead V1, V2, or V3 - 3 points;
- ST elevation ≥ 5 mm in a lead with a negative (discordant) QRS complex - 2 points.
- ≥ 3 points = 90% specificity of STEMI (sensitivity of 36%).

Although the original Sgarbossa criteria were an important first step in correcting this problem, the study had 3 important limitations. First, they depend on a point system that relied on 3 findings, only 2 of which would provide enough points to make the diagnosis of AMI.

Second, Sgarbossa *et al*. used the outcome of acute myocardial infarction (diagnosed by creatine kinase-MB elevations) instead of angiographic evidence of acute coronary occlusion, which limits the sensitivity of the rule because it combines non-ST segment elevation myocardial infarction and ST-segment elevation myocardial infarction. Third, Sgarbossa *et al*. used an absolute criterion (5 mm) rather than a proportional criterion for excessively discordant ST elevation (in the opposite direction from the QRS complex). Not surprisingly, attempts to validate electrocardiographic criteria for AMI in LBBB have shown useful specificity but poor sensitivity (21, 22, 23).

In order to improve accuracy, Smith *et al*. derived the "modified Sgarbossa criteria", in which the absolute 5-mm criterion for excessively discordant ST elevation is replaced with a proportion (ST elevation/S-wave amplitude ≤ -0.25). Smith *et al*. used angiographic outcomes to define acute coronary occlusion (thereby excluding NSTEMI). This outcome was more relevant to the reperfusion decision. They reported superior diagnostic properties of the modified criteria compared to the original criteria in their derivation study (7).

Mayers *et al*. performed an external validation of the modified Sgarbossa criteria by comparing the diagnostic accuracy (in terms of sensitivity and specificity) of the original and modified Sgarbossa criteria for the identification of acute coronary occlusion in patients with LBBB. They concluded that the modified criteria were superior to the original Sgarbossa criteria for the diagnosis of acute coronary occlusion in LBBB. They believe that it is currently reasonable to begin in corporation the modified Sgarbossa criteria into practice as a supplementary clinical judgment (23).

The diagnostic approach and management strategy for STEMI have evolved in the last decade with primary PCI currently the preferred reperfusion therapy (4). This has produced abundant angiographic evidence about false catheterization laboratory activation. One of the most important study was conducted by Larson *et al*. The aim of the study was to determine the prevalence, etiology and outcomes of false-positive cardiac catheterization laboratory activation in patients with a suspected STEMI by three criteria: no culprit coronary artery, no significant coronary artery disease and negative cardiac biomarker results. Of the 36 patients who presented with a new or presumably new LBBB from a regional STEMI registry, 16 (44%) did not have a culprit coronary artery, 10 (27 %) had no significant coronary artery disease and 13 (36%) had negative cardiac biomarker results. Thirty-day mortality of these patients was 8.3% (24).

Chang *et al*. analyzed a cohort of patients who presented to emergency departments with suspected acute coronary syndromes. According to the electrocardiograms, patients were classified in LBBB not known to be old (new or presumed new LBBB), LBBB known to be old or no LBBB. From all 7937 patients included in the study, 55 had new or presumed new LBBB, 136 had old LBBB and 7746 had no LBBB. They did not find a difference in the rate of clinical AMI between patients

with a new or presumably new LBBB, old LBBB, or without an LBBB (7.3% *vs.* 5.2% *vs.* 6.1%, P = 0.75). Only 19.2% of patients with new or presumably new LBBB had documented coronary disease by angiography and 7.8% underwent coronary revascularization, at 30 days of follow-up. The conclusion of this study was that the presence of LBBB, whether new or old, did not predict AMI, but coronary artery disease (19.2% *vs.* 11.9% *vs.* 10.1%, p = 0.0004) and revascularization (7.8% *vs.* 5.2% *vs.* 4.3%, p = 0.04) were more common in patients with new or presumed new LBBB (25).

More recently, Jain *et al*. evaluated the hypothesis that new or presumably new LBBB in symptomatic patients frequently leads to an overdiagnosis of acute myocardial infarction. A total of 892 patients from a single-center STEMI registry were admitted with initial diagnoses of STEMI and only 36 patients (4%) had new or presumably new LBBB on their presenting electrocardiograms. Only 14 patients (39%) had final diagnoses of acute coronary syndromes, of which 12 were AMI, while 13 (36%) had cardiac diagnoses other than acute coronary syndrome and 9 (25%) had noncardiac diagnoses (16).

The angiographic studies mentioned before, suggest that new or presumably new LBBB provides limited diagnostic value in identifying patients with acute coronary occlusion and should not be considered a reliable indicator for STEMI. In this case, in the early fibrinolytic trials it is logical to postulate that a significant proportion of those patients with LBBB and suspected AMI did not have an occluded culprit artery and thus received inappropriate fibrinolysis. Such false catheterization laboratory activation exposes patients to unnecessary procedure-related risks, prolongs hospital stay, increases health care expenses, and imposes a burden on limited resources.

Between January 2011 and December 2013, we conducted a study at the Cardiology Clinic of the Cardiovascular Disease Institute "Prof. Dr. George I.M. Georgescu", Iaşi, which included 477 patients with the left bundle branch block, from which 319 patients had a new or presumably new left bundle branch block, and 158 had an old left bundle branch block. If coronary angiography was performed in 80.56% of patients with new LBBB, only 18.35% of patients with old LBBB were evaluated by coronary angiography. Nearly half of the patients with new LBBB had significant angiographic coronary lesions, most commonly single- or bicoronary lesions (15.67% and 12.22%), with frequent localization at the left anterior descending artery (32.91%). However, nearly 80% of patients with old LBBB (79.11%) did not have significant angiographic coronary lesions, and when they were present, they most frequently involved all three main coronary arteries (10.76%) (26,27).

In another study, Pera *et al*. enrolled a total of 3903 consecutive patients with suspected STEMI who presented to a PCI center, including 131 patients (3.3%) with new LBBB. Patients with new LBBB were older, more commonly women, with a history of previous MI or coronary artery bypass grafting (CABG) and more frequently presented with cardiac arrest or heart failure. A culprit lesion was present less frequently in patients with new LBBB compared to those without (54.2% *vs.* 83.3%; $P<0.001$), consistent with the finding of more patients with TIMI 2 or 3 flow pre-PCI (79.5% *vs.* 51.9%; $P<0.001$) and fewer having PCI performed (51.2%

*vs.*79.0%; $p<0.001$). They concluded that patients with acute ischemic symptoms and new LBBB represent a high-risk patient population with unique clinical challenges, and emergent angiography and primary PCI should be considered the optimal strategy. Delaying reperfusion therapy for patients with suspected STEMI and new LBBB is likely to reduce the benefits of revascularization in patients with an acute culprit lesion (18). This was also the conclusion of another prospective study published by Farre *et al*. They evaluated the incidence and outcome of patients with LBBB referred to primary angioplasty and compare them with patients with ST segment elevation. From 4593 patients included in the study, only 2.6% (120 patients) had LBBB. Only 35.8% (44 patients) with LBBB underwent a primary percutaneous coronary intervention for thrombotic coronary artery occlusion, in opposite to 85.8% of patients with STEMI, $p < 0.0001$. Also, there was a statistically significant difference between the final diagnosis of patients included in the study, because 89% of patients with ST-elevation had the final diagnosis of acute coronary syndrome, compared to only 44% in LBBB, $p< 0.001$ (28).

Evaluating the implications of left bundle branch block in acute cardiac events based on a 23-year registry, Alkindi *et al*. concluded that patients with LBBB were less likely to have acute myocardial infarction regardless of the presenting symptoms, compared to patients without LBBB. The most frequent cause of admission with LBBB was congestive heart failure (54.2%), followed by ST-segment elevation myocardial infarction (13.3%). Overall, acute myocardial infarction was diagnosed in 32% of non-LBBB patients *vs.* 21% of LBBB patients, with a statistically significant difference between these groups ($p = 0.001$) (29).

One of the most recent and important study regarding the diagnosis of acute myocardial infarction in the presence of left bundle branch block was published by Nestelberger *et al*. They prospectively evaluated the incidence of acute myocardial infarction in patients presenting with chest pain to 26 emergency departments, a total of 8830 patients, 2.8% (247 patients) with LBBB. They found no difference in the incidence of acute myocardial infarction between patients with known LBBB *vs.* those with presumably new LBBB (29% *vs.* 35%, $p = 0,42$), MI being the final diagnosis in 30% of patients with LBBB (30).

RIGHT BUNDLE BRANCH BLOCK

It is known that both patients with left ventricular conduction disorder and patients with right ventricular conduction disorder in the context of acute myocardial infarction have a poor prognosis and increased mortality (31,32,33). However, there are only a few studies that compared the prognosis of patients with suspected acute myocardial infarction and left and right bundle branch block.

For example, in a retrospective study involving 6742 patients with acute myocardial infarction, Widimsky *et al*. analyzed the angiographic characteristics of patients with acute myocardial infarction and right bundle branch block and compared them with those presenting with LBBB or with other electrocardiographic pattern (11). Of these, 3447 patients were diagnosed with STEMI and 907 with NSTEMI. Only 291 patients had LBBB, 427 patients had a right bundle branch block, the remaining 1670 patients had acute myocardial infarction with other electrocardiographic changes.

Transluminal primary percutaneous coronary angioplasty was performed in 80.1% of patients with RBBB *vs.*. 68.3% of patients with LBBB, with statistically significant differences between the two groups of patients, p = 0.004. The morbidity of patients with RBBB was more than double compared to STEMI mortality, respectively 14.3% for patients with RBBB, 13.1% for LBBB patients and 5.4% for patients with STEMI (p = 0.004). The conclusion of this study was that RBBB should strongly be considered as a standard indication for reperfusion therapy, in the same way as LBBB.

Recent, Wang *et al*. conducted a meta-analysis to evaluate the prognostic value of RBBB in AMI patients (13). They identified five studies of 874 patients and evaluated the prognostic value of new-onset RBBB in AMI. The results show that new-onset RBBB is associated with an increased long-term mortality (RR, 1.66, 95% CI [1.31-2.09], p = 0.000), and higher risk of ventricular arrhythmia (RR, 4.86, 95% CI [2.10-11.27], p = 0.000), and cardiogenic shock (RR, 2.76, 95% CI [1.66-4.59], p = 0.000), but not heart failure in patients with AMI. Previous RBBB may have more relations with heart failure than new-onset RBBB in AMI patients. Based on the basic characteristics of the included studies, patients in previous RBBB group have a higher median age and more comorbidities (hypertension, diabetes mellitus, etc.), especially previous myocardial infarction and previous angina. It may explain the higher proportion of heart failure in previous RBBB group (13). They concluded that revascularization therapies should be considered when persistent ischemic symptoms occur in patients with RBBB, especially with new-onset RBBB (13).

Other studies (11,34,35) have shown that new-onset RBBB in AMI subjects often suggest LAD lesion, proximal occlusion of coronary artery and large infarct size. It is also associated with more complications including heart failure, arrhythmias, and increasing mortality compared with non-RBBB group.

In another recent study, Li *et al*. (36) evaluated the clinical characteristics and the value of new onset right bundle branch block in the early reperfusion therapy for patients with acute myocardial infarction. They included a total of 845 patients with AMI subjected to primary coronary angiography, seventy patients (8.28%) presented RBBB and 56 (6.63%) presented LBBB. Compared with non-BBB patients, RBBB patients had a higher incidence of smoking, hypertension and diabetes, hyperlipidemia, worse heart function and higher peak enzyme level (P<0.05). Compared with LBBB patients, the RBBB patients were almost male, and have a lower incidence of smoking, hypertension and diabetes, and a lower peak enzyme level (P<0.05). In 54.29% of RBBB patients and 42.86% of LBBB patients (54.29 *vs.* 42.86%, p<0.001) the infarct related artery was anterior descending artery, while the right coronary artery was responsible for 38.57% of myocardial infarction in RBBB patients and 32.14% in LBBB patients. Most of the patients with new RBBB and new LBBB had anterior and/or high-lateral wall myocardial infarction (58.57% *vs.*. 55.36%), and the second localization of myocardial infarction was inferior and/or right ventricular for patients with RBBB and inferior and/or posterior wall for patients with LBBB (34.29% *vs.* 28.57%, p = 0.032). The cumulative one-year survival rate in RBBB patients was significantly lower than

those in the no BBB group ($p = 0.046$) and the LBBB patients ($p < 0.001$). As RBBB is associated with more severe symptoms, a higher incidence of complete occlusion of infarct related artery and a lower one-year survival rate, the conclusion of this study was that new onset RBBB should be considered as an indication of emergency revascularization (36).

The new European Society of Cardiology guideline for ST-segment elevation myocardial infarction recommends that left and right bundle branch block should be considered equal for recommending urgent angiography in patients with suspected myocardial infarction, but the level of evidence is not high. In fact, the presence of RBBB may lead to the misdiagnosis of transmural ischemia and mask the early diagnosis of ST-elevation myocardial infarction. Also, new-onset RBBB is occasionally caused by AMI (4). Moreover, they consider that in patients with LBBB, ST-segment elevation $\geq$ 1mm concordant with the QRS complex in any lead may be an indicator of acute myocardial ischemia. In patients with RBBB, new or presumed new ST-segment elevation $\geq$ 1mm, or ST-segment or T wave abnormalities (excluding leads V1-V4), may indicate acute myocardial ischemia (4). This ESC recommendation is based on a sole publication by Widimsky *et al*., which reported an association of RBBB and coronary artery occlusion.

To evaluate this novel recommendation of urgent angiography in patients with left or right bundle branch block and suspected myocardial infarction, Newmann *et al*. (37) conducted a prospective study and included a number of 4067 patients presenting to the emergency department with suspected myocardial infarction. In the overall study population 846 of 4,067 (20.8%) patients were adjudicated as having acute MI. In the ECG analyses RBBB was observed in 125 (3.1%), LBBB in 281 (6.9%) and bifascicular block in 60 (1.5%) of all patients, while 3601 patients had no complete bundle branch block. The final diagnosis of myocardial infarction was adjudicated in 20.8% (RBBB), 28.5% (LBBB), 23.3% (bifascicular block) and 21.6% (no complete block) of patients. To assess mortality, all patients were followed for up to two years, and they observed that the mortality rate after one year was 10.7% (RBBB), 7% (LBBB), 17.5% (bifascicular block) and 3.2% (no complete block). Patients having a RBBB were equally likely to have a final diagnosis of MI and to receive revascularization as those without bundle branch block. In contrast, patients with LBBB had a higher rate of MI diagnoses. Nevertheless, patients with RBBB represent a high-risk population with a high mortality rate. The clinical implications of this study are significant, as the rate of RBBB among patients with suspected MI is low, the final diagnosis of MI in patients with RBBB is equally likely when compared to patients without bundle branch block and the presence of RBBB is associated with adverse outcomes, but they disappear after adjustment for confounders (37).

There are also other studies that highlighted the association between new onset RBBB and acute coronary syndrome.

Timoteo *et al*. evaluated the differential impact of LBBB and RBBB in prognosis at one-year follow-up, after an acute coronary syndrome. From a total of 3990 patients included in the study, 3.4% had LBBB and 4.3% RBBB. Even if the medical treatment was similar, patients with bundle branch block were less often submitted to angioplasty. Bundle branch block patients had worse outcome ($p < 0.001$), but similar in

LBBB and RBBB (p = 0.597). Also, both LBBB and RBBB were predictors of all-cause mortality at one-year follow up in a univariate analysis, and after adjustment only RBBB remains an important predictor (HR 1.66, p = 0.007). The results of this study support the European guideline recommendation that we should pay special attention to patients with bundle branch block and treat them as least as aggressively as patients with a normal QRS duration (38).

In a recent article, Shaikh *et al*. (39) presented four cases of new RBBB associated with chest pain and critical lesions of the left anterior descending artery, highlighting the need to consider new RBBB in the setting of acute chest pain, as an indication for acute reperfusion therapy also in the American guidelines, as the European Society of Cardiology guideline recently implemented.

CONCLUSIONS

In conclusion, we consider that patients with persistent ischemic symptoms, and presumed new LBBB or RBBB that is not rate-related, have an adverse prognosis and they should be evaluated by emergency angiography.

NEWS

CHEST COMPUTED TOMOGRAPHY AND COVID -19 DISEASE

COVID-19 (coronavirus disease 2019) is an infectious disease caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2. Definitive diagnosis of COVID-19 requires a positive PCR test. Multiple radiological organizations have stated that computed tomography (CT) should not be relied upon as a diagnostic or screening tool for COVID-19. Current best practice advises that chest computed tomography is not used to diagnose COVID-19, but maybe helpful in assessing for complications. The non-specific imaging findings are most commonly of atypical or organizing pneumonia, often with a bilateral, peripheral, and basal predominant distribution. According to Fleischner Society (April 2020) CT imaging is not indicated in patients with suspected COVID-19 and mild clinical features unless they are at risk for disease progression and is indicated in a patient with COVID-19 and worsening respiratory status. Patients requiring CT should receive a non-contrast chest CT (unless iodinated contrast medium is indicated). If iodinated contrast medium is indicated, for example a CT pulmonary angiogram (CTPA), a non-contrast scan should be considered prior to contrast administration, as contrast may impact the interpretation of ground-glass opacification patterns. The most frequent findings on CT are bilateral, subpleural, peripheral ground glass opacities, crazy paving appearance, air space consolidation, bronchovascular thickening in the lesion, traction bronchiectasis. A SYSTEMATIC REVIEW OF THE INCIDENCE AND RISK FACTORS FOR HEPATITIS E INFECTION IN ROMANIA (Abstract): The incidence of viral hepatitis E (HEV) has taken shape in European countries, economically developed areas and with a high level of hygiene. For the occurrence of this disease was initially incriminated the consumption of properly unprocessed pork or travels to endemic areas. Over time, other ways of transmission were discovered. The spread of the virus also included Romania. In this context, we aim to analyze data from the literature on the incidence and risk factors for HEV. Recent studies conducted in Romania have shown a seroprevalence between 9.6% and 50% in farms, highlighting a zoonotic transmission. Another study shown that the risk factors associated with HEV infections were previous blood transfusions, immunosuppressive disorders, or hepatitis B virus co-infection. In conclusion, HVE infection remains an undeclared disease, possible due to misdiagnosis, subclinical infection, or co-infection with another hepatitis virus. **Keywords**: HEPATITIS, ZOONOTIC TRANSMISSION, ENDEMIC DISEASE.

Hepatitis E (HEV) is an international public health problem (1). The infection is caused by hepatitis E virus (HEV), single-stranded, single-serotype, RNA virus belonging to the *Herpesviridae* family. Five HEV genotypes are known to cause human disease (2). Genotypes 1, 2, 4 and 5 are associated with illness in developing countries, genotype 1 and to some extent genotype 2 being associated with large waterborne outbreaks. HEV genotype 3 has been implicated in the occurrence of hepatitis E in developed countries (3).

The disease was identified in the 1980s as a result of outbreaks of non-A, non-B hepatitis in Africa and Mexico. The outbreaks were caused by a disorder with clinical and paraclinical manifestations of an acute hepatitis. Thus, appears HEV, a new type of hepatitis with enteral transmission. Subsequently, the infection broadens its horizons over time, appearing in regions with a high level of hygiene (Europe, North America, Australia), economically developed countries (4).

From the beginning, the route of transmission of the virus has been considered the fecal-oral route, through the consumption of drinking water and contaminated food, in less developed geographical regions, such as South-east Asia, Africa and Mexico, where it continues to evolve to a

high endemic level (5). The appearance of the infection in high-income countries, led to numerous hypotheses regarding the mode of transmission. Initially, travel to endemic areas and ingestion of contaminated food and zoonotic transmission was criminalized (6). Subsequently, it was found cases in non-endemic areas unrelated to the two factors mentioned above. Blood transfusions, organ transplants and contact with infected animals have also been reported (7). Thus, further research was needed to discover the risk factors associated with hepatitis E in non-endemic areas.

In most patients, hepatitis E causes a self-limiting illness that lasts for several weeks. Acute infection is generally asymptomatic. Regarding clinical hepatitis E infections and severe forms, it has been observed that they are more common in middle-aged and elderly men, who often have other coexisting diseases (8).

Although there are data in the literature describing and analyzing hepatitis E virus infection among different population groups, little is known about the actual sources of infection, routes of transmission and risk factors for the host (such as associated diseases and chronic treatment of the patient) regarding acute hepatitis E in Romania.

MATERIAL AND METHODS

This study is a retrospective analysis of the scientific literature regarding HEV. We included in the study articles published in medical journals that focus on the incidence and risk factors associated with HEV. We focused our attention on articles made in Romania, excluding those made in other geographical parts of the world.

We searched on electronic databases for articles on HEV incidence, seroprevalence and risk factors in Romania. The most used online databases were *PubMed, Scopus, ISI Web of Science, Google* research with no limitations placed on year of publication and language restriction. We used keywords like hepatitis E virus, HEV RNA, genotype, zoonotic transmission, enterically transmission, seroprevalence, Romania. And critically reviewed appropriate publications to extract consistent findings, identify knowledge gaps, and suggest future studies.

RESULTS AND DISCUSSION

Hepatitis E virus infection is not very common in our clinical practice, but the incidence is increasing. In Romania, the first research about HEV infection appeared in the 2000s and was limited to seroprevalence studies of specific anti-hepatitis E IgG. The earliest results shown a seroprevalence rate of 5.9% in the general population (9) and of 12% among patients with hepatitis B or C (10).

In 2010, in a report of the results of a study performed on students (mean age: 22.91 ± 0.56 years) and medical staff (mean age: 36.71 ± 8.88 years), the prevalence of these antibodies was 12.5%, respectively 14% (1,11).

Subsequently, several research were carried out by veterinarians on the evidence of hepatitis E virus infection in pigs and the population in the northeastern part of Romania. The results showed a seroprevalence of 17.14% (12/70) and 12.82% (10/78) in the tested human sera. In 2011, the youngest age group (9-20 years) tested negative, whereas as older age groups (> 20 and > 40 years) had seroprevalence of 28.6% and 12.9%, respectively. In 2012, the youngest age group (18-45 years) had seroprevalence of 6.25%, whereas the older

groups had the seroprevalence up to 28%. In the same research, it was found that HEV infections were found in middle-aged adults exposed to the virus through contact with pig farms. This confirms the potential role of the animal reservoir in the occurrence of this zoonosis, while also suggesting that the hepatitis E virus is found in a ubiquitous manner in pig farms in north-eastern Romania. Moreover, anti-HEV IgG was more prevalent in women (15.78%) than in men (10%) (12-14).

Other recent research in Romania has found an anti-HEV Ac IgG seroprevalence between 9.6% and 50% in farms, in farm pigs and wild boars in which PCR (polymerase chain reaction) analysis in a small number of liver samples and the spleen found only genotype 3, similar to neighboring countries. Data (in small samples) on the seroprevalence of Ac IgG anti HEV in humans are rare and variable: general population (5.9% - 28%, higher in older participants), students and medical staff (12.5-13.98 %) and patients with hepatitis B or C (12%) (15).

Another study, published in April 2019 in the Romanian Journal of Laboratory Medicine, aimed to identify the risk factors associated with HEV seropositivity. The group consisted of patients admitted to the National Institute for Infectious Diseases "Prof. Dr. Matei Balș" from Bucharest, Romania and included 175 patients. Forty-six patients (23.3%) had positive anti-HEV IgG antibodies, with a mean age of 54.5 years. The associated risk factors were previous blood transfusions (22.7%), immunosuppressive disorders (40.9%) and hepatitis B virus co-infection (31.1%) (16).

A systematic review of the published literature on the distribution of hepatitis E in South-Eastern Europe has shown that anti-HEV seroprevalence varies widely. Statistical data in different population groups from Romania ranged from 5.9% to 17.1% (17).

In early 2020, a study on hepatitis with enteral transmission over a period of 2 and a half years was published. The results show that the incidence of HEV has increased compared to previous years. The number of people diagnosed with HEV was 48, the mean age was 50.6 years and two-thirds of the patients were men. Laboratory data showed that patients with hepatitis E had significantly less modified AST and ALT, bilirubin, prothrombin index and INR levels. Severe forms were found in 12 (25%) of hepatitis E patients, of whom 3 died. Ribavirin treatment was initiated in 9 patients with acute-chronic hepatitis E, immunosuppression, cancer, or neurological manifestations, with good results (15).

There are few studies on HEV in humans, and new data are needed to define the characteristics and the real incidence of HEV infection. Studies performed on animals show the presence of anti-HEV IgG in farm and backyard pigs with high seroprevalence rates.

CONCLUSIONS

Most of the studies we have found in the literature study the seroprevalence of the infection, showing the increase in the incidence in economically developed areas. Zoonotic transmission and its appearance are predominant in middle-aged males.

However, in clinical practice this pathology is not very common. The use of different methods for the diagnosis of hepatitis and the increased incidence of HVE among asymptomatic patients, can make this pathology go undiagnosed. This may also be possible due to misdiagnosis

or double hepatitis.

Raising awareness of the importance of thermal food preparation, boiling drinking water and washing vegetables is an effective intervention to prevent hepatitis E infection.

TUBERCULOSIS AND BACTERIAL CO-INFECTIONS IN CHILDREN (Abstract): Tuberculosis is a major public health problem nowadays without a change to be eliminated in many regions. The study aim was to evaluate the bacterial co-infections diagnosed in children with TB, in a hospital in the eastern part of Romania. **Material and methods**: The study group consisted of 37 children diagnosed with TB and various bacterial co-infections and admitted in a pediatric hospital in Galati County, Romania, between 2014 and 2017. **Results**: In our study group characterized by the mean age of 10.40, with a male/female report = 0.94, a predominance of children aged 12-17 (45.94%), and no cases were recorded in 0-1 year of age group, the most frequent localization of TB lesions was pulmonary TB primoinfection (45.86%), bacterial pneumonia was the main co-infection in children with TB (64.86%), then bacterial acute bronchitis (28.73%) and gastroenteritis (5.41%). **Conclusions**: Our study evidenced that bacterial pneumonia was the most frequently diagnosed co-infection in children with TB (64.86%). The most frequent bacterial co-infections pathogens were *E. coli* (32.43%), *S. pneumoniae* (27.03%), and *K. pneumoniae* (21.62%) and the length of stay between 4 days and 92 days. **Keywords**: TUBERCULOSIS, PEDIATRICS, BACTERIAL CO-INFECTION, PREVALENCE.

According to WHO reports on the *END TB* strategy, in the present worldwide, the average rate of decrease in the incidence of tuberculosis (TB) was 1.6% per year between 2000-2018, and 2.0% between 2017 and 2018. The cumulative decrease between 2015 and 2018 was only 6.3%, considerably lower than the targets specified by the WHO that stipulated reductions of 20% by 2020. TB mortality was reduced by 11% in the period 2015-2018, these figures representing less than a third of the strategy objectives, however, in the WHO European region, countries are close to achieving the goals of the phase of TB elimination in 2020, because the TB incidence decreased by 15% and mortality by 24% (1).

Recently, WHO published estimates of child-specific diseases for the first time in 2012, reporting approximately 500,000 cases of TB among children under the age of 15 years. These figures were based on extrapolations from adult data, which were heavily weighted on sputum smear positivity and did not incorporate sufficient adjustments to account for under-detection and under-reporting in pediatric populations. Similarly, the estimated pediatric mortality from TB is poorly quantified, and in 2015, the WHO estimated 210,000 deaths from TB among children. In many countries with high mortality, deaths from

TB are often reported to be caused by pneumonia or meningitis (2, 3, 4).

The risk of active TB is higher in people suffering from other diseases that affect the immune system. For example, children with malnutrition are three times more at risk, and in 2018, 2.3 million new cases of TB associated with malnutrition were reported worldwide (5).

Age such as very young children, male gender and low socio-economic status can be factors favoring infection, along with malnutrition, poor living conditions, active or passive smoking (in young children) or associated infections (HIV / AIDS) (6, 7).

The study aim was to highlight the bacterial co-infections diagnosed in children with TB, in a hospital in the eastern part of Romania.

MATERIAL AND METHIODS

The cross-sectional study was conducted on a group of 37 patients admitted in the pediatric unit of The Hospital of Pneumology, Galati, Romania, during January 1st, 2014 and December 31st, 2017. The total number of children admitted in the study interval was 208, our study group representing 17.78% of total TB admitted cases. The inclusion criteria were pediatric age groups and suspicion of diagnosis of TB and the association of at least one microbiologically confirmed bacterial co-infection. The exclusion criteria were patients over 18 years old and no suspicion of co-infection with TB.

Statistical analysis consisted in the calculation of frequency, mean, linear regression ANOVA regression, Pearson's correlation between variables. The *p* value was set <0.05.

RESULTS

Demographic characteristics. The study group of children diagnosed with TB was characterized demographically by a mean age of 10.40 (minimum = 4; maximum = 17), with a homogenous distribution regarding gender: 18 females (48.64%) and 19 males (51.36%); M/F = 0.94. Distribution by age groups showed a predominance of children aged 12-17 years old (17 cases - 45.94% of total), following by 6-11 age group (13 cases – 35.13%) and 2-5 age group (7 cases – 18.93%). No cases were recorded in 0-1 age group (fig. 1).

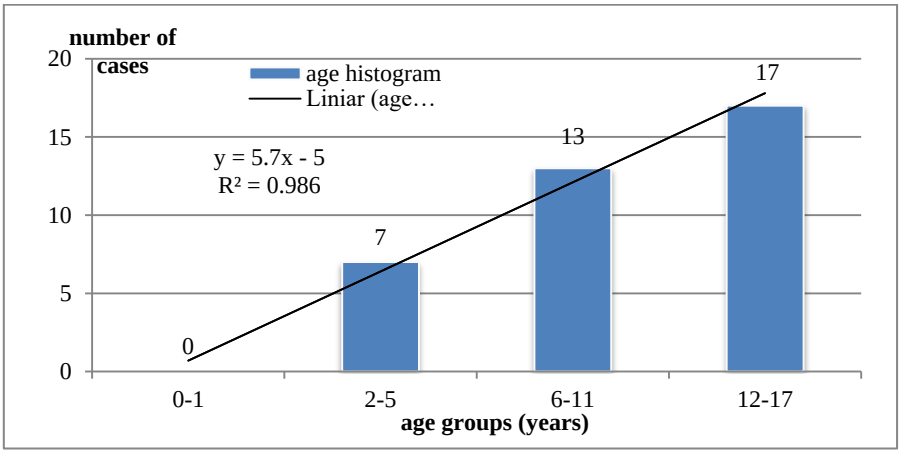

Fig. 1. Age histogram

Localization of TB lesions. The most frequent localization of TB lesions was pulmonary TB primoinfection (17 cases – 45.86%), then ganglionary infection (14 cases – 37.83%) and pleurisy (6 cases – 16.21%) (fig. 2).

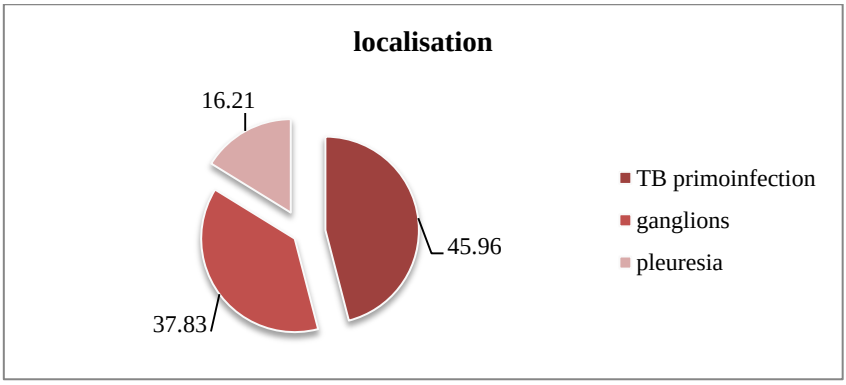

Fig. 2. TB localization

Bacterial co-infections. Bacterial pneumonia was the main co-infection with TB in children (24 cases – 64.86% of total), then bacterial acute bronchitis (11 cases – 28.73%) and gastroenteritis (2 cases – 5.41%) (fig. 3).

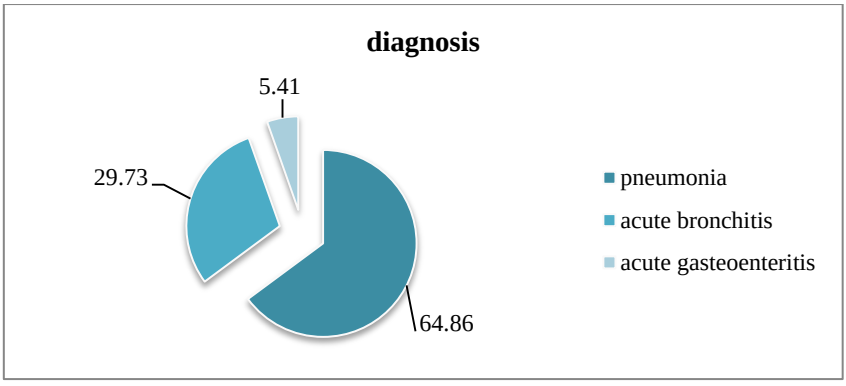

Fig. 3. Bacterial coinfections diagnosis

The bacterial co-infections pathogens were identified by microbiological methods as: *Escherichia coli* (12 cases – 32.43%); *Streptococcus pneumoniae* 10 cases – 27.03%); *Klebsiella pneumoniae* (8 cases – 21.62%); *Hemophilus influenzae* (5 cases – 13.51%); *Staphylococcus aureus* (2 cases – 5.41%) (fig. 4).

Hospitalization days. Pediatric patients with TB and bacterial co-infections were hospitalized a total number of 1567 days with a mean = 44.78 days, a minimum = 4 days (a 12-year female patient with pulmonary TB and acute bronchitis with *S. pneumoniae*) and a maximum of 92 days (a 11-year-old female patient with ganglionary TB and acute bronchitis with *H. influenzae*). Length of stay was 1-4 days in 1 case

(2.7% of total), 5-10 days in 6 cases (16.21%), 11-30 days in 5 cases (13.51%), 31-60 days in 14 cases (37.85%) and >60 – 92 days in 12 cases (32.42%) (fig. 5).

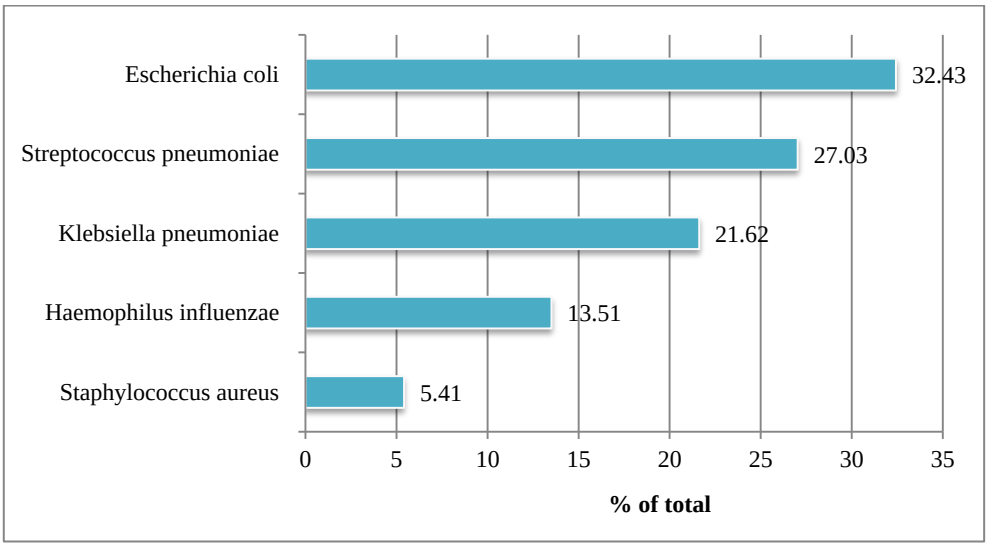

Fig. 4. Pathogens involved in bacterial coinfections in pediatric patients with TB

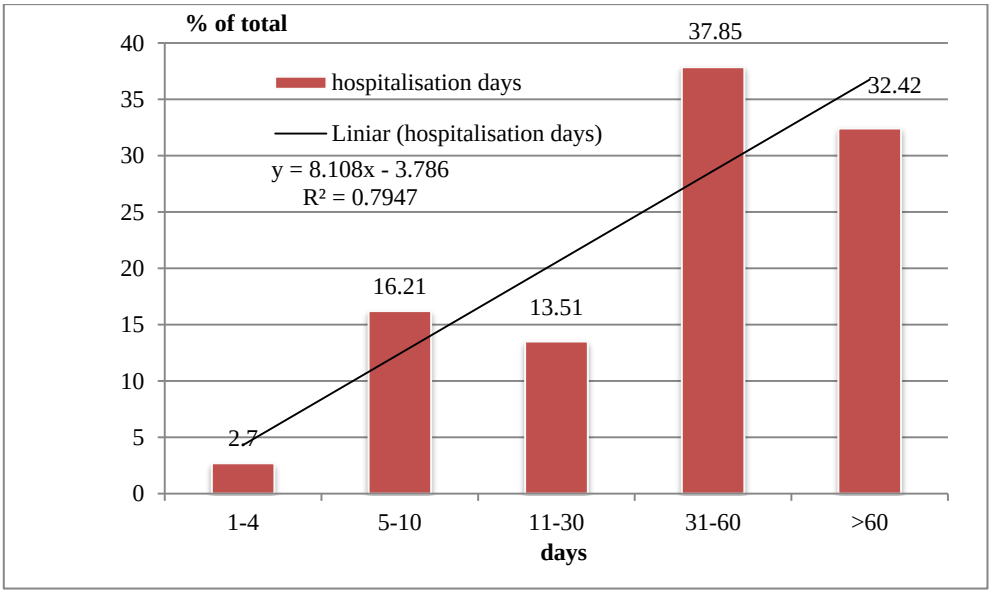

Fig. 5. Hospitalization days of patients with TB and bacterial coinfections

By applying *ANOVA linear regression*, a weak correlation between the age of the patients and the number of days of hospitalization (r = 0.1289) was revealed, but statistically non-significant (significance F = 0.44; p = 0.44).

DISCUSSION

TB occurs as a result of infection in previously uninfected people is called primary TB. Pulmonary TB in children, especially in young children, continues to be almost exclusively primary TB. A significant number of TB cases in adolescents and young adults are often the consequence of a recent infection, although the clinical and radiological picture suggests a secondary TB (primary and secondary tuberculosis). Primary occult TB infection, often ignored, is the most common of the clinical forms; the first manifest simple infection, in which the radiological examination identifies the primary TB complex (with satellite adenopathy). Primary infection with benign complications in which the primary complex is associated by local complications with benign evolution such as serofibrinous pleurisy and primary infection with serious complications, with a significant fatality rate such as bronchopneumonia are other important clinical forms. Secondary tuberculosis, specific to adulthood, is characterized by the predominance of cavitary forms and chronic clinical evolution. The clinical elements, regardless of location, only partially guide the diagnosis, in TB it is necessary to corroborate epidemiological, clinical and laboratory data (8).

Although TB is a preventable disease requiring coordinated systematic efforts, the prevalence is in fact the iceberg of the epidemiological burden and a child with active TB represents a sentinel event in the community, reflecting the intensive transmission among all the individuals. (2) Clinical symptoms of TB in children are often nonspecific, leading to a delayed diagnosis and a long period when the child is contagious and without specific treatment to prevent secondary transmission (9), and during this time the child, often immunosuppressed, is exposed to the pressure of the circulating community pathogenic flora, often aggressive and with a high level of antibiotic resistance (10).

There are few published studies on the burden of bacterial TB co-infection in the general populations of countries with a high prevalence of TB (11). Studies provided evidence that co-infection of other respiratory bacteria in children with TB was easily quantifiable, although the high rate of co-infection observed in people infected with TB might overestimate the real prevalence in all TB patients. The Gram-negative bacteria are, overall, the most commonly non-mycobacterial pathogens identified in patients with TB. Our data are consistent with published data of other studies (12, 13, 14).

Simultaneous occurrence of TB and bacterial co-infection in patients might be uncommon, according to a recent study. A triple infection of HIV/AIDS, TB, and pneumococcal pneumonia has been reported, the former being a crucial predisposing factor for the co-infection of TB and other bacteria, mainly pneumococcal pneumonia (15, 16, 17).

In populations where TB has a high prevalence, there is also co-infection of TB and bacterial pathogens. Differentiating TB from other lesions such as bacterial pneumonia is a clinical challenge, as it is difficult to diagnose TB in childhood. A study in Cambodia showed that 9% of all patients and 33% of patients with TB evaluated for respiratory symptoms, in whom sputum was collected and tested for *M. tuberculosis* and microbiological suffered from TB and bacterial co-infection, and *K. pneumoniae* and *Pseudomonas aeruginosa* were the main bacteria detected in the Asian study (12).

In contrast to the Asian study, we iden-

tified that *E. coli* and *S. pneumoniae* as the main bacterial co-infection pathogens involved in pediatric patients.

The strengths of our study are that we assessed bacterial co-infections associated with TB in children who come from open communities, where they come in contact with people with favorable factors, receptive to the disease. The weaknesses and the limitations of our study could be the small group of patients assessed for a few demographic variables and the non-inclusion into the evaluation the symptoms and other clinical features as well as the characteristics of bacterial antibiotic resistance.

CONCLUSIONS

Our study evidenced that bacterial pneumonia was the most frequently diagnosed co-infection in children with TB (64.86%). The bacterial co-infections pathogens were *E. coli* (32.43%), *S. pneumoniae* (27.03%), *K. pneumoniae* (21.62%), *H. influenzae* (13.51%), and *S. aureus* (5.41%).

The length of stay for pediatric patients with TB and bacterial co-infections consisted in a total number of 1567 days, with a minimum of 4 days and a maximum of 92 days.

The study team intends to continue the research on larger group of pediatric patients, considering the missing data exposed above. The results of further similar and improved studies could be extrapolated in the hospital management and community information regarding TB and bacterial co-infection prevention and best therapy protocol.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest and they received no specific funding regarding this scientific research.

ATRIAL FIBRILLATION STRUCTURAL SUBSTRATES: AETIOLOGY, IDENTIFICATION AND IMPLICATIONS

AF is the most common sustained cardiac rhythm disorder and is associated with increased morbidity and mortality. Since the first description of AF initiation by triggers from pulmonary veins sleeves, pulmonary vein isolation (PVI) has become the standard ablation strategy in patients with AF. However, freedom from the arrhythmia, particularly in non-paroxysmal AF, remains suboptimal, and it is now clear that, in these patients, AF is maintained by an atrial substrate beyond the pulmonary veins. Although electrical remodeling may be reversible with termination of the arrhythmia, the development of atrial substrate due to fibrosis contributes to the progression of the AF phenotype from paroxysmal to persistent AF, leading to an arrhythmia that is more refractory to intervention. It is clear from animal and human studies that prolonged AF can cause this structural change. Moreover, it is also apparent that a range of risk factors associated with AF, including age, obesity, heart failure (HF), valvular heart disease, hypertension (HT), sleep apnea and alcohol intake, may also progress atrial remodeling. The rise in the prevalence of cardiovascular risk factors (particularly driven by ageing populations and the obesity epidemic) has been associated with an increase in the prevalence of AF and AF-related hospitalizations. In this review, the authors focus on insights from electrophysiological mapping studies in cohorts with AF risk factors. They also discuss substrate mapping and its implications for AF management and outcomes (Al-Kaisey AM, Parameswaran R and Kalman JM. Atrial Fibrillation Structural Substrates: Etiology, Identification and Implications. *AER* 2020; 9(3): 113-120).

ACTUAL STATUS IN BRAIN MAPPING

Starting from 1900 with the wide-known Broadmann mapping until present times with large-cohort functional studies, neuroscientists and neurosurgeons were looking for dividing the cortex in its areal components. The importance of this brain mapping is clearly stated: establishing the role and function of each brain area would facilitate diagnostic analysis, enhance comparisons between studies and people, improve quality of surgeries and facilitate statistical brain analysis.

In this editorial, authors have performed an analysis of the current status of brain mapping taking into consideration both general and particular data. Our aim was to provide the basic concepts to each of the aforementioned investigations and finally look at the present perspective on some of the wide-recognized brain mapping projects.

CYTOARCHITECTONIC – BROADMANN & MYELOARCHITECTONIC – VOGT

Cytoarchitectonic analysis is based on the different dimensions, distribution and shape of the cells that form the various aspects of the cerebral layers. Korbinian Broadmann may be one of the first most renowned scientist who attempted to divide the human cortex into areas based on the assumption that each of them has a different cytoarchitecture (1909). Even though his map was a pioneering approach in the domain at that time, now it is well known that it doesn't match the actual representation of brain mapping. Studies after Broadmann have changed completely the way to analyze brain. This included a completely different way of defining brain boundaries based on statistics and not on visual inspection, various staining and imaging techniques, larger samples analysis, 3D representation maps and probabilistic maps to analyze brain variability (1).

Another subdiscipline similar to the first one described is myeloarchitectonic which focuses on analyzing the distribution and orientation of single axons within the cerebral cortex. Cecile and Oskar Vogt (2) alongside their disciples published a lot of literature work in this domain. These data were recently gathered into a meta-analysis and transferred to their neuroanatomical sequence in a new representation (2). Individual mappings were superimposed, and the boundaries were averaged. Finally, their 180-areas-map exceeded the number of the areas of any other map that was done before: Brodmann (43), Von Economo and Koskinas (107), Sarkissov (71). Nowadays, myelin density is analyzed using longitudinal, relaxation rate, T1w/T2w mapping (3, 4). In these cases, the spatial difference in myelin content across brain areas becomes a measure for delimitating putative cortical boundaries. Age and localization of the cortical layer may affect myelin density. For example, people between 18-22 years have higher myelinated areas and inner layers showed higher T1w/T2w ratio (5).

TASK-BASED fMRI

Functional MRI (fMRI) imaging based its processing on the blood oxygen level dependent (BOLD) contrast mechanism. During fMRI scanning one subject could perform different tasks or rest. Task-based fMRI analysis concentrates its focus on brain activity during task performance. The

fMRI results depend on the relation between the level of attention of the subject to avoid motion that would increase the artifacts and achievement of statistically significant data for analysis (6). When analyzing brain activation, it should be considered that level of integration depends on the specific task demand. The strength of connections between core and peripheral areas within a network changes depending on the task. In stimulated areas functional connectivity patterns could be predictive factors for task identification (7). Other times, task-based fMRI showed to be useful in identification of altered brain areas, following mild brain injuries. Thus, Cook et al. demonstrated based on tfMRI that middle frontal gyrus neural activity alteration is responsible for loss of memory and attention (8).

Conventional, task-based fMRI (tfMRI) includes a single-task paradigm for each brain function, whose strategy varies: block design, event-related or mixed design. The first one uses equitemporal blocks and rests to elucidate the response, while in the second case, the events are presented randomly and focus on a specific cognitive event. Blocked design showed to be robust to the hemodynamic changes with great statistical power and to permit resting intervals yet may miss transiently activated regions. In contrast, event-related requires complex analysis and relies more on the linearity of BOLD responses, but allows shorter and randomly alternating trials, having a broader associative signal detection (9, 10).

RESTING-STATE fMRI

Resting-state fMRI (rsfMRI) assumes that in lack of any task, different connected regions may express similar patterns of BOLD signal following specific circuits, including somatosensory, visual and auditory networks. This specific particularity differentiates rsfMRI from tfMRI, in which different paradigms are designed for identification of each particular system. Moreover, rsfMRI has access to a broader range of patients and pathologies that cannot correctly perform the tfMRI (11). Back to the low-frequency signals, these are traditionally considered noises which are expressed under rest condition and may be dependent on the resting-state networks (RSNs) or may be independent of the neuronal activity. The argument in favor of the first statement is that these fluctuations recapitulate the functional track that is activated during specific task or appear in brain areas with activation relevance. Regarding the second option, BOLD-like signals may appear also due to head movement or vascular CO2 concentration fluctuation; specifically hypercapnia leading to an increase in BOLD-like signal, and hypocapnia to a decrease in BOLD-like signal (12).

DIFFUSE TENSOR IMAGING

While many brain investigations elucidate functions or different areal brain behavior, Diffuse Tensor Imaging (DTI) shows more accurate the actual relationship between different brain areas, providing a structural map of the brain tracks (13). Advancement in modern techniques has broaden the investigation of brain fibers.

Diffusion of water molecules is characterized by anisotropy (not the same movement in all directions of 3D space) dependent on the orientation of the fiber tracts modulated at a micro and macro level, specifically, being more hindered on the perpendicular axis rather than on the parallel axis (14). Density of the fibers, myelination, individual fiber diameter are important aspects to be considered. The orientation of the primary diffusion tensor within each voxel forms the primary vector (the eigenvector) of the voxel that by inter-voxel connectivity establishes the axis of

the tracked fibers (15).

BRAIN MAPPING AND NEUROSURGERY

Functional MRI has a lot of appliances in medicine, including neurosurgery. From the very beginning, fMRI can be used as a tool to prevent the injury of brain structures while removing tumors, especially in awake surgeries when the patient is asked to perform specific tasks that will activate the areas. By creating the functional brain map, neurosurgeons could determine how close the tumor is to the areas responsible for speech, movement, hearing.

Connectome analysis of resting-state fMRI could be used to determine the active areas in the brain, also called nodes, which can be find isolated or in segregation forming hubs and generally measures the intelligence index or how efficiently our brain integrates the information between areas. The existence of hubs demonstrates that selective small-nodes removal could be more efficient in preserving brain function during a tumor surgical resection than gross-total targeted removal. Another perspective is the "connection at risk" , or how much will affect an extended margin removal to the surrounding areas and to the patency of long connection within the hemispheres (16). Brain tumor resection has been demonstrated to trigger changes in the small-world distribution supported by rapid and real-time brain network integration. The degree of sparsity in the network has changed between pre- and postoperative group and decrease in the correlation degree was related to decrease in neurocognitive capacity (17).

In epileptic surgery, eloquent cortex responsible for motor, language and memory should be preserved as much as possible, thus, task-based fMRI is used to determine the active areas prior to surgery. Language fMRI could predict the decline in cognitive function after lobe excision and it is considered to be a better alternative to the classical Wada test (18). Beside the classical artifacts, preoperative fMRI could encounter some challenges as the anti-epileptic medication and long-term seizures could alter area activation during fMRI image acquisition and decrease Intelligence quotient (IQ). Another challenge is that seizures could alter localization and lateralization of language and memory function. Since language is a complex function of the brain, at least two block design paradigms should be addressed to the patient. Sentence Completion, Silent Word Generation, Rhyming, Object Naming, Antonym Generation and Passive Story Listening are some paradigms that activate middle frontal gyrus (the expressive region) and temporal lobe (the receptive region) recommended by the American Society of Neuroradiology (19). Regarding memory fMRI, left frontal and anterior medial temporal activations correlates with greater postoperatively verbal decline than bilateral posterior hippocampal activation considering the fact that left lateralization is more often encountered (20). In children, early onset of seizures modifies the normal lateralization, while the brain is focused on saving the vital cognitive functions. While memory fMRI was used frequently in adults, language fMRI was rarely used in children, based on the false assumption that either adults or children manifest co-lateralization of memory and language. However, recently, novel paradigms combining both block and event-related analyses are used to assess the memory outcome in pediatrics (21).

Increased neural adaptive plasticity has been observed in patient undergoing diffuse low-grade gliomas surgery (DLGG), leading to low neural disturbances prior and after surgery. Changes in functional activity patterns after surgery, even though

they are few in this case, were analyzed, anatomical and functional. Mean DO80 scores were similar in the pre- and postoperative group suggesting that each brain is responsible for its reorganization (22). Resting-state fMRI combined with direct electrical stimulation (DES) during awake surgery showed that brain areas affected by electrical stimulation during surgery are directly linked to areas responsible for cognitive functions, identified preoperative on fMRI. This combined approach reduces the restriction of each method and highlight the importance of functional mapping (23). MRIs were used for creating a probabilistic map that provides insights regarding the tumor behavior dependent on the location and the likelihood of a tumor to appear at some location (24).

CONCLUSIONS

From the first cytoarchitectonic maps of the 20th century until the large-scale functional MRI studies of the present times, brain mapping has encountered major changes in data acquiring and processing. As mentioned in this article, each of the investigation came with different pros and cons.

Resting-state connectivity which has been tested initially in predefined areas, currently is used for boundary mapping, allowing whole brain parcellation, control testing and identification of areas subdivisions. Graph theory integrates brain activity as a complementary tool for boundary mapping. Adaptation to the classical methods lead to more flexible thresholds for defining areas boundaries. While rfMRI and tfMRI demonstrate brain parcellation based on functional brain activation, DTI elucidates the actual relation between brain areas based on the underlying white matter structure.

Currently, by combining all of these methods into a multimodal approach, scientist have achieved the past century-objective obtaining an unprecedented representation of at least 180 brain areas per hemisphere. In this review, the authors aimed to provide an actual status of the brain mapping methods that would serve other scientists to understand better the basic concepts of this field.

TRADITIONAL CARDIOVASCULAR RISK FACTORS AND CANCER - COINCIDENCE OR CORRELATION?

Cardiovascular and neoplastic pathologies are two entities that cause a huge "burden" for the public health system. It is estimated that there are currently 15 million people suffering from cardiovascular disease and 14 million patients with a history of neoplastic disease, with risk factors and common biological links underlying the pathophysiological mechanisms of both entities (1).

In recent decades, there has been a significant improvement in the survival rate of certain cancers and a steady increase in the number of survivors diagnosed with cancer. Cardiovascular complications encountered in these patients are common, having a profound impact on both morbidity and mortality, so that their identification and management have become important elements in the general care of cancer patients (1, 2). There has also been an overlap in the prevalence of cancer and cardiovascular diseases as well as the development of cancer therapies in many elderly patients, with a higher load of comorbidities, especially of a cardiovascular nature (3, 4). For this reason, the approach of the neoplastic patient as a whole requires a different level of complexity. Heart disease and cancer, although apparently two distinct conditions, share a number of common elements, including risk factors, genetic, metabolic and inflammatory components, as well as common prevention strategies. Together, they are the most common causes of death in the United States (5). In recent years, the synergistic link between cardiovascular diseases (CVD) and cancer has become increasingly evident through the existence of common risk factors, most of which are modifiable and traditional, such as smoking, obesity, diabetes, type of diet, sedentary lifestyle and alcohol. There are also studies that have highlighted potential common biological mechanisms (inflammation, oxidative stress and an increased release of oxygen free radicals, hormonal factors, cytokine release, growth factors, metabolic reactions), as well as the influence of active therapies for cancer on risk factors (6, 7).

It is admitted that even cardiovascular disease can itself predispose to the occurrence of some forms of cancer (e. g. heart failure) through much more complex mechanisms than the mere presence of traditional risk factors.

However, with the progress in oncology, the life expectancy of these patients increases with a simultaneous increase in the cardiovascular risk due to hypertension, dyslipidemia, metabolic syndrome, acute coronary syndromes, pathologies generally associated with old age. Thus, compared to the general population, a cancer survivor has a 7 times higher risk of CVD mortality, a 15 times higher risk of heart failure and a 10 times higher rate of CVD (6,7).

Smoking

It is one of the major cardiovascular risk factors, whose presence increases the risk of occurrence of CVD (especially ischemic) 2 to 4 times, the risk of stroke and peripheral arterial disease, but at the same time increases the risk of bronchopulmo-

nary cancer 25 times (1). To these is added the existence of a causal relationship with at least 11 other types of cancer (breast, stomach, pancreas, bladder) (1-5). Moreover, smoking cessation is associated with a 50% reduction in coronary heart disease compared to those who still smoke after only 1 year and a 50% reduction in the risk of cancer of the mouth, throat, esophagus and bladder after 5 years. After 10 years of smoking cessation, bronchopulmonary cancer mortality decreases by 50% compared to those who continue to smoke. The percentage of deaths caused by both cancer and coronary heart disease, which can be attributed to smoking and which has been reported in various studies in the United States, is about 30% (1, 6, 8). Beyond the cardiovascular and neoplastic risk, smoking is associated with a prothrombotic status that amplifies the risk of thromboembolic events and, on the other hand, obscures the prognosis of neoplasia.

Arterial Hypertension

Hypertension and dyslipidemia are two major risk factors for CVD; however, the results are somewhat divergent in their involvement as independent risk factors for cancer. Among patients with neoplasms, hypertension and dyslipidemia are common. Under the conditions of some common risk factors, the two pathologies show an increased co-prevalence, which makes it difficult to identify the sequence of their occurrence (1). A recent meta-analysis that included over 140 individual studies confirmed the existence of a causal relationship between hypertension and an increased risk for various cancers, including: kidney, colorectal, breast, endometrial, liver and esophageal cancer (9). The reverse relationship is also known. Cervical radiotherapy for certain types of cancer, through the injury of carotid baroreceptors and the secondary increase in sympathetic activity may be associated with hypertension. At the same time, chest radiotherapy for various cancers is associated with an increased risk of coronary heart disease; this risk increased fourfold when a history of hypertension was included (10).

An increase in the prevalence of hypertension has been reported in relation to the use of chemotherapy and adjuvant medication in cancer. Angiogenesis inhibitors (bevacizumab, sorafenib and sunitinib), corticosteroids, erythropoietin as well as non-steroidal anti-inflammatory medication are associated with an increase in blood pressure (1, 9, 10). Similarly, adult patients with autologous hematopoietic stem cell transplants with a history of hypertension who received high-dose anthracycline therapy (≥ 250 mg/m^2) had a 35-fold increased risk of heart failure (12).

Increasing the life expectancy of neoplastic patients frequently implies an increase in the incidence of hypertension, which draws attention to the importance of early detection and treatment, both as a risk factor for cancer and as an adverse effect of the associated treatments.

Dyslipidemia

The important role of cholesterol and triglycerides in maintaining the structural and functional integrity of cell membranes is known, while participating in the development, cell multiplication and stability of DNA structures. Thus, the role of dyslipidemia in cancer was studied, either as a predisposing factor for neoplasia or as a side effect. A significant association was identified between elevated LDL-cholesterol (LDL-c) levels and an increased risk for prostate cancer, with elevated HDL-cholesterol (HDL-c) values proving

to be a protective effect (13). The same lipid profile was correlated with the risk of breast cancer (14).

LDL-c is the fraction most prone to oxidation under pathological conditions, with oxidative stress resulting in increased levels of lipid peroxidation products that can alter the structure of cellular DNA. At the same time, HDL-c is a powerful antioxidant by counterbalancing the oxidative harmful effect of LDL-c, thus potentially becoming an anticarcinogenic. At the same time, it has been shown that elevated serum triglycerides are associated with decreased ligands for sex hormones, resulting in increased serum levels of free estradiol involved in breast cancer (15).

On the other hand, cases of cancer associated with hypolipidemia have also been reported, either by the secondary impairment of the lipid metabolism, or by the direct hypolipidemic effect of tumor cells, or by the treatments with antioxidant vitamins used in cancer (16). This inverse relationship between the lipid profile and neoplastic risk has been proven especially for head and neck cancers, with mortality being significantly higher in patients with low cholesterol (17). Also, cancers in the gynecological sphere and especially the ovarian one is mentioned as being associated with decreases in lipid values (18). The importance of these data comes from the usefulness of the lipid profile as an early diagnostic marker in neoplasms. In the relationship between dyslipidemia and neoplasms, it is worth mentioning the impact of cancer therapy on the lipid profile, with the concomitant influence on the cardiovascular risk. Thus, antiandrogen therapy in prostate cancer has been shown to be associated with significant increases in cholesterol and triglycerides (18,19). Also, some medications (bexarotene, asparaginase, corticosteroids) used in hematological neoplasms can significantly alter the lipid profile, these patients even needing plasmapheresis to avoid severe complications (acute pancreatitis). Hormone therapy such as tamoxifen may have a mixed effect on the lipidogram, with a decrease in total cholesterol and LDL-c levels, but with an increase in the values of triglycerides, which may contribute to more frequent thromboembolic events (20).

Statins are the basic treatment in dyslipidemia, with a proven role in the primary and secondary prevention of cardiovascular diseases (acute coronary syndromes, strokes, thromboembolic events). At the same time, however, due to their anti-inflammatory properties, induction of apoptosis, inhibition of tumor growth, angiogenesis and metastases, these drugs seem to have a synergistic action with chemotherapy in improving the prognosis in cancer (7). Statins have been reported to have a role in preventing breast cancer recurrence due in part to the reduced levels of an estrogen receptor ligand (27-hydroxycholesterol), which has been shown to regulate tumor growth dependent on this type of receptor (21). At the same time, in a study of over 12,000 participants, statins were shown to be useful in reducing mortality in patients with bronchopulmonary cancer (22). Moreover, recent studies are focused on the effects of statins in reducing the incidence of cancer. The results in this direction are contradictory. However, large meta-analysis studies have not yet shown statistically significant results regarding the role of statins in the prevention of neoplasms (23).

The study of the lipidogram in neoplastic patients also acquires a prognostic role. A 2017 meta-analysis of the prognostic significance of lipids in cancer identi-

fies elevated HDL-c and total cholesterol as positive prognostic markers for the survival of these patients (24). In the study of breast cancer, elevated LDL-c values correlated with disease progression, being a negative prognostic factor (25, 26). The negative prognostic value of LDL-c has been demonstrated for small cell lung cancer, prostate cancer, colorectal cancer and esophageal cancer (27-30). Triglycerides have also been shown to be an independent prognostic factor in the progression of hepatocellular carcinoma (31).

Diabetes mellitus

Diabetes is another well-established risk factor for CVD. In a meta-analysis that included 820,900 people from 97 prospective studies, diabetes was associated with an increase in cardiovascular mortality, but also in that caused by cancer, especially liver, pancreatic, ovarian, colorectal, pulmonary, bladder and breast (1, 32). Although individuals with diabetes appear to be at an increased risk of developing more than one type of cancer, it is unclear whether this link is causal or through common risk factors, including obesity, via insulin resistance as an intermediate pathophysiological mechanism. The strongest epidemiological data for a direct causal link between diabetes and cancer have been observed in breast cancer, intrahepatic cholangiocarcinoma, colorectal cancer and endometrial cancer (33). An increased prevalence of type 2 diabetes has been found, especially in patients with colonic polyposis located in the proximal colon and, especially in male patients (34).

Obesity

Obesity is an independent risk factor for CVD, cancer and diabetes, and is usually associated with other risk factors including high blood pressure and dyslipidemia (7). In 2012, increased body mass index (BMI) values were associated with approximately 500,000 new cancer cases worldwide, becoming the second risk factor after smoking in most Western populations (1, 35). Obesity has been associated with an increased prevalence of digestive (esophageal, colorectal, biliary tract, pancreatic), hormonal (breast, endometrial), renal and multiple myeloma neoplasms, data confirmed by the study of 204 meta-analyzes (1,36). The pathophysiological relationship between cancer and obesity is mainly explained by several mechanisms: insulin resistance associated with obesity, increased bioavailability of insulin-like growth factor (IGF-1) and elevated levels of endogenous estrogen (1, 37). Overweight and obesity at the time of cancer diagnosis appear to increase the risk of cancer reoccurrence and reduce the survival duration (38). An important thing to remember is the association of obesity with a prothrombotic status which in turn is responsible for the occurrence of thromboembolic events (especially pulmonary thromboembolism) in the postoperative period. The predisposition for a status of hypercoagulability in the postoperative period is enhanced in the neoplastic patient who also associates obesity.

Sedentarism

Physical activity (especially isotonic exercise) reduces the risk of CVD, all-cause mortality and certain types of cancer, including colon, breast and endometrial cancers (39). In a recent analysis that included 1.44 million participants, increased physical activity and smoking cessation were associated with a significantly lower risk of developing several types of cancer, including leukemia, esophageal, lung, kid-

ney, myeloma, rectum and bladder (39). Physical activity after the diagnosis of cancer has also been associated with a lower recurrence of cancer (40).

Malnutrition

Unhealthy eating habits have a significant impact on both cardiovascular risk factors and the appearance of various forms of cancer (especially digestive) (1, 41). The PREDIMED study (*Prevención con Dieta Mediterránea*) was a randomized controlled study that confirmed the observations of previous studies by demonstrating a 30% reduction in the risk of stroke, myocardial infarction and death from cardiovascular causes in those patients undergoing a Mediterranean diet, rich in extra virgin olive oil or walnuts (1, 42). A reduction in the incidence of breast cancer has also been observed in patients receiving a Mediterranean diet (42). Meta-analyzes of prospective cohort studies have repeatedly shown that consumption of red meat and processed meat increases the risk of cancers of the digestive tract, especially the colorectal tract, by 20-30% (43). A 2010 study found that inadequate eating habits were the leading cause of both mortality and decreased quality of life in patients with neoplasms (44).

Alcohol

The relationship between alcohol consumption and CVD is somewhat controversial due to a J-shaped "historical association" in observational studies in which light alcohol consumption appears to have a protective role on the occurrence of ischemic heart disease (especially red wine by vasodilation and growth of HDL-cholesterol levels) (1). However, the overall impact of alcohol consumption on CVD is still detrimental, with around 780,000 deaths from CVD due to global alcohol consumption (1, 45). The main harmful effects of alcohol consumption are more clearly defined as a causal relationship with at least seven types of cancer: oropharynx, larynx, esophagus, liver, colon, rectum and pre- and post-menopausal breast cancer. The combined consumption of tobacco and alcohol has a marked multiplier effect on cancers of the oropharynx, larynx and esophagus (45). Cardiac damage, even subclinical, due to alcohol may become manifest at the time of chemotherapy, accentuating its cardiotoxic effects (tachycardia, ventricular arrhythmias). Also, in the presence of more severe heart damage due to alcohol, such as dilated cardiomyopathy, an initially low left ventricular ejection fraction may make it difficult or even contraindicate the administration of chemotherapy.

The risk of cardiovascular disease in cancer survivors

Due to the increase in cancer survival, as a result of the emergence of modern therapies, but also their cardiotoxic potential, CVD occurs with increasing frequency among patients with neoplasms. Traditional individual cardiovascular risk factors, such as high blood pressure in a cancer survivor, appear to pose a higher risk than high blood pressure in a person with no history of cancer. In addition, each additional cardiovascular risk factor encountered in a cancer survivor appears to increase the risk of CVD to a greater extent than a simple additive effect (11).

Cancer survivors are prone to have an increased risk of CV morbidity and mortality in all age groups and have a higher percentage of traditional CV risk factors compared to age-appropriate control groups (47, 48). The Ontario Cancer Registry

evaluated 98,999 women with early-stage breast cancer and found that the risk of death at 10 years was higher in people with a history of CVD (1, 47, 48).

In conclusion, traditional individual cardiovascular risk factors in a cancer survivor amplify the overall risk. Cancer survivors are more likely to have an increased risk of CV morbidity and mortality in all age groups and have a higher percentage of traditional CV risk factors compared to the age-appropriate control groups.

OLD AND NEW CHALLENGES FOR THE SCIENCE OF NUTRITION

At a quick search in a dictionary, one can find that nutrition is "the biochemical and physiological process by which an organism uses food to sustain its life; it includes ingestion, absorption, assimilation, biosynthesis, catabolism and excretion" (*Encyclopedia Britannica*) (1). However, the term nutrition also means "the science that studies the physiological process of nutrition (primarily human nutrition), interpreting the nutrients and other substances in food in relation to maintenance, growth, reproduction, health and disease of an organism" (2).

Is the science of nutrition the result and/or a component of a multidisciplinary, interdisciplinary or transdisciplinary system?

Today, teamwork is required in any medical, educational, social, or political field. This means common or compatible objectives, working methods and evaluation methods that ultimately prove their benefits and effectiveness. In research, multiple disciplinary approaches on the same continuum are encouraged to create hypotheses, develop studies that provide accurate perspectives on real-life issues, and possibly consensus. Many epistemologically distant disciplines can together provide answers to a complex issue. The terms interdisciplinary, multidisciplinary and trans-disciplinary, although they seem interchangeable terms, have their own definitions.

Multidisciplinary relies on knowledge from different disciplines, which remain within their limits. Professionals in these fields work independently on a common research issue from the perspective of their own discipline, each offering their own point of view. The conclusions are *additive* to each other. Consulting *Oxforddictionaries.com* we find that the adjective multidisciplinary describes "combining or involving several academic disciplines or professional specializations in approach to a topic or problem".

Interdisciplinarity analyzes, synthesizes, combines and harmonizes the links between disciplines in a coordinated and coherent whole. The conclusions are *interactive*, each discipline being able to affect the research results of the other, creating a new level of integration. According to *Oxforddictionaries.com* the adjective interdisciplinary describes "of or relating to more than one branch of knowledge".

Transdisciplinary *holistically* integrates the natural, social and health sciences in a humanistic context that transcends their traditional boundaries. The result can be a kind of xenogenesis in which the new creation of the integration of disciplines can be something completely new.

From these interactions new domains can crystallize. We can refer here to biochemistry, nanotechnologies, etc. The science of nutrition itself has needed, and still benefits from, the contribution of physiology, biophysics, genetics, and other basic sciences to understand the mechanisms, metabolic pathways, and their responses to malnutrition or overeating (3). The term "nutrition" encompasses biological as well as sociological aspects of how the human body accesses the substrates and cofactors necessary for normal conception, growth, development and aging.

In recent years, the term "convergence research" has also been introduced, which is a new term that integrates fields that have historically been distinct scientific and technological disciplines. "Multidisciplinary

research is the foundation of interdisciplinary and convergence research" (4).

Nutrition as an interdisciplinary field could also be included as an example of translational medicine. "Translational medical science, preclinical research, evidence-based research, or disease-targeted research, [is the] area of research that aims to improve human health and longevity by determining the relevance to human disease of novel discoveries in the biological sciences" (5).

Nutrition includes the two areas of translation, namely applying the findings of laboratory studies to the development of human studies and contributing to research aimed at improving the adoption of best practices in the community (guidelines) (6).

Nutrition has been called multi-, inter- or trans-disciplinary in numerous scientific articles and even in documents disseminated in the social media. It must be seen as a scientific culture of great complexity that faces problems that transcend the paradigm of disciplines (7).

As a science, nutrition is "young" (8). The first visible advances were seen at the end of the 18th century, when the laboratory methods of the "chemistry revolution" were applied to build new knowledge. For example, Antoine Lavoisier and Pierre-Simon Laplace showed that the slow combustion of organic compounds in tissues produced heat. The first controlled interventional clinical study was performed in 1746 by James Lind, on sailors suffering from scurvy. Twelve sailors, with a similar severity of the disease, were divided into pairs and, for 2 weeks, each pair was offered one of the recommended treatments at that time. The sailors who received lemons and oranges were almost healed after only 6 days. However, the cure for scurvy was not in fact found for many years, because it was not possible to store either lemons/oranges or their juice for such a long time on ships (to be given as a preventive food) and it was wrongly assumed that citric acid was the cure (9).

It was the era when attempts were made to understand the causes/ways of transmitting of diseases and to comprehend the ability to predict, control and manage life. The pursue for detailed knowledge of macronutrients and energy balance began. It was soon showed that it was not enough to meet the caloric requirements without considering the sources. The experiment of François Magendie at the beginning of the 19th century remains famous: he fed dogs with a single food considered "preeminently nutritious" which covered the energy needs. Whether it was sugar, olive oil or butter, the animals invariably died after a month. His conclusion, still valid today, was that "diversity and multiplicity of foods is an important rule of hygiene; which is, moreover, indicated to us by our instincts" (10).

Later, remedies for other diseases with a single nutrient deficiency such as pellagra, scurvy, beriberi, goiter, xerophthalmia, rickets or nutritional anemia were sought. In the first half of the 20th century, the role of vitamins and minerals was discovered and described, and the notion of *Recommended Daily Intake* (RDI) was established. The name *vitamin* is attributed to Casimir Funk, who in 1913 found that some foods contained a "vital amine" (11). Nutritional strategies were established to prevent/combat micronutrient deficiencies. A whole industry of synthetic vitamins, multivitamins, fortified foods, and food supplements was developed. Their marketing and use to protect against deficiency were successful, especially in rich countries. Unfortunately, this led to a reductionist model of scientific research based on addressing unique/singular nutrients, on identifying and isolating the element involved, on evaluating its physiological effect and quantifying the optimal level of intake to prevent

the disease. Nutritional guidelines were similarly focused on the benefits of unique nutrients.

After World War II, the gap between high-income and poor/developing countries widened. If in the former chronic diseases of the plethora began to appear, in the latter malnutrition and diseases of deficit remained predominant. For these countries, projects continued (scientifically unsustainable today) such as providing caloric foods and covering the "protein gap". Starting from the legitimate desire to produce more basic, energy-dense and affordable foods, some agricultural crops (wheat, rice and corn), farms (cattle) and industries (fortification of foods or even milk formulas) were subsidized (12). A nutritional imbalance was thus produced, with the consumption of mainly cheap food, but the global "hunger" was still not possible to combat. Many nutritional problems were still unresolved with important clinical implications. Poor nutrition has led to poor health, and this has led to poor nutrition.

If the prevalence of diseases of deficit has decreased, it has been observed that excess calories and dietary imbalance have led to increased cardiometabolic risk and the development of atherosclerotic pathology, type 2 diabetes and cancer. The growing burden of non-communicable nutrition-related diseases has begun to worry, which has led to new research directions such as dietary fats and sugar. Unfortunately, the current which concluded that protective diets should be *low-fat* has won and it has taken 3-4 decades to prove the futility and even danger of such recommendations (13). This mistake also stemmed from the reductionist view and the desire to find a unique nutrient, guilty of illness. Subsequently, nutritional study models were sought to be adapted to the research of chronic non-communicable diseases. Research into the complex, synergistic actions between nutrients and other food constituents has led to the study of food patterns. For this, modern statistical methods have been used (principal component analysis, cluster analysis, reduced rank regression). It should also be noted that many statistical tools are experiments from the field of nutrition (e.g., Fisher's exact test, known as "lady tasting tea" or student test – Gosset's from the Guinness Brewery). The study of food patterns has shown strong associations between prudent diets and health and between "Western" diets and atherogenesis. The study of factors associated with food patterns with risk can provide arguments for decision makers in medicine/society to implement successful nutritional interventions.

The number of population studies have multiplied in search for the links between diet and disease, the interactions of food consumption with the human body. Even a new branch of epidemiology has been developed -nutritional epidemiology- which seeks a thorough understanding of the science of nutrition in order to identify dietary risk factors for disease and provide specialists with reasoned targets for preventive measures (14).

Nutritional epidemiology faces many challenges and problems, some of which are methodological (study design, data collection and processing) and interpretation (statistical difficulties/lack of validated statistical methods, the risk of creating false cause-effect relationships).

Randomized nutritional intervention studies are not as common in research because diet is closely linked to multiple aspects of life, exposure time is long, there are practical and ethical obstacles in selecting and assigning subjects to specific diets, and there are many confounding factors in interpreting the relationship between eating habits, health and lifestyle (15).

Simultaneously with the multiplication and scale of nutritional studies (especially observational), their reporting to the public increased, even before the verification of the rigor of some scientific conclusions.

Thus, a binary characterization of foods into "good" and "bad" with adverse implications has been created, instead of considering the dietary needs of populations of different cultures. This leads to misconceptions, myths and fad diets.

The burden of nutritional diseases is on the shoulders of health systems, populations and governments. Diseases and suffering caused by a combination of declining physical activity and unbalanced, low-nutritional density diets are prevalent worldwide. The double burden of malnutrition refers to the coexistence of malnutrition and overweight/obesity, but in fact there are three dimensions of malnutrition: malnutrition, overnutrition and micronutrient deficiencies, with individual, family, national or global impact (16). Mapping the current state of malnutrition, which is complex and multidimensional, must be correlated with contextual determinants such as health and education systems or socio-economic status in order to have any chance of reducing the severity and duration of this burden. The lives of malnourished children, whether with stature hypotrophy ("stunting"), weight hypotrophy ("wasting") or micronutrient deficiencies, are characterized by a reduced ability to resist disease, to study and to progress throughout life. All forms of malnutrition throughout life or for generations impose increased metabolic burdens on limited homeostatic capacity (16).

Non-communicable diet-related chronic diseases have become endemic, being identified in the *Global Burden of Disease 2017* study as being responsible for 73% of the world's deaths (17). The double burden of malnutrition, as well as the spread of non-communicable chronic diseases, can be explained by the nutritional transition (but also the demographic and epidemiological transitions) related to biology and the obesogenic environment (food, economic and socio-cultural) (18). Consumption of ultra-processed, energy-dense, hyper-palatable foods and sugary drinks are among the causes of weight gain (19). The approach should be twofold: historical and biological, and the solution should be political and through structured programs.

Most countries face multiple disease burdens: the persistence of infectious diseases, malnutrition and maternal mortality, the challenges of chronic non-communicable diseases, and issues directly related to globalization, such as pandemics and the consequences of climate change on health (20). Especially on low- and middle-income countries, there is a threefold burden of: communicable diseases, non-communicable diseases and road accidents. Three other pandemics - "obesity, undernutrition, and climate change - represent The Global Syndemic that affects most people in every country and region worldwide. They constitute a syndemic, or synergy of epidemics, because they co-occur in time and place, interact with each other to produce complex sequelae, and share common underlying societal drivers" (21).

The science of nutrition must be concerned with promoting and maintaining the nutritional health of individuals, families, and communities. The mission of nutrition is research, education, and contribution / involvement in supporting the health and food security of the population, as fundamental human rights. It involves the acquisition and synthesis of knowledge in the field of nutrition but also its dissemination to other professionals and to the population.

Educational strategies for healthy eating and nutrition promote the creation, accumu-

lation, and dissemination of the values of nutrition science, the initiation of evidence-based programs and policies to encourage society's organized efforts to use resources wisely, to enable sustainable access to nutritious and safe food (22). Unfortunately, today we have to fight with a lack of confidence in politics, in our economic way of life and even in science and medicine (23). There are also optimistic messages. Two of the United Nations' 17 Sustainable Development Goals for 2030 are zero hunger and good health, and others address extremely relevant nutrition indicators: improving sanitation and access to clean water, reducing poverty, inequity, and inequality; increasing access to education, productive work, and health services (24).

In a world that is undergoing radical transformations, new challenges and opportunities appear for the science of nutrition. The responsibility for making efforts lies not only with the small group of nutrition professionals, but with society as a whole. Food remains the strongest lever for optimizing health and environmental sustainability. Creating and managing a complex program for achieving/maintaining health means using all available evidence in developing common local, regional, and global strategies and partnerships for implementation, not only between scientists and specialized agencies but also between countries with different levels of development.

NEWS

VITAMIN D AND RESPIRATORY VIRAL INFECTIONS INCLUDING COVID-19

Vitamin D helps in decreasing the pro-inflammatory cytokines in the lungs. Due to its immunomodulatory function, it increases the anti-inflammatory and antiviral responses of the respiratory epithelial cells during an infection. Now more than ever, treating patients with Vitamin D is vital, mainly because of its various beneficial effects (innate immunity boosts) against viral diseases and potential role in decreasing the mortality associated with the cytokine storm in COVID-19 patients. Giving Vitamin D supplements in the autumn and winter months to high risk patients could add an extra layer of protection against the development of respiratory tract infections, especially during the COVID-19 pandemic. Even though the evidence suggests that vitamin D has anti-inflammatory and antiviral properties, further investigation is needed (such as randomized double-blinded controlled trials) in order to better understand the relation between Vitamin D and COVID-19. (Balla M, Merugu GP, Konala VM, Sangani V, Kondakindi H, Pokal M et al. Back to basics: review on vitamin D and respiratory viral infections including COVID-19. *J Community Hosp Intern Med Perspect* 2020;10(6):529-36).

EDITORIAL

METABOLIC EVALUATION OF THE KIDNEY STONE PATIENT - THE KEY FOR PERSONALISED METAPHYLAXIS

Kidney stones represent one of the "oldest" diseases and have affected normal people but also great historical characters starting from Ramses II to George W. Bush or Lionel Messi. Despite progress in understanding the pathophysiology of kidney stones, we are witnessing an increase in the incidence and prevalence worldwide. The spread of urinary stones disease is not homogeneous on the planet, its epidemiology is influenced, among other things, by external factors such as geo-climatic conditions. In the United States, the prevalence between 1976-1980 was 3.8%, it increased to 5.7% between 1988-1994, while in late 2010 already reached 8.8% (1). Meanwhile in Europe, given that there are climatic differences, but also in terms of eating habits between different areas, it is expected that the prevalence of urinary stones will differ between countries or regions. In a relatively hot region like Andalusia, according to Arias Vega *et al*., in people aged 40 to 65 years old, the prevalence of lithiasis in 2016 was 16.4%, while in Europe's northern regions like Iceland the incidence between 2005-2008 was 138/100.000 according to Edvardsson *et al.* (2, 3).

However, climatic conditions alone cannot be blamed for increasing the number of lithiasis patients in the Eurasian area. According to Novikov *et al.,* after the collapse of the Soviet Union, the transition to a Western-style diet rich in sodium and proteins, as well as access to modern diagnostic methods, led to a dramatic increase in the incidence and prevalence of urinary stones in the current Russian Federation (4). The authors note that from 1980 to 2008 the incidence of urolithiasis increased almost 12 times from an average of 53/100,000 inhabitants (even 17 / 100,000 inhabitants in the Moscow area) to 609.3/100,000 inhabitants. However, the distribution of cases is quite heterogeneous. The highest increase in incidence was in the Russian far East between 2002 and 2008 from 529.9 to 714.7/100,000 inhabitants and the lowest in 2002 in the Ural Federal District (Okrug), respectively 360.6/100,000 inhabitants. The increase in the frequency of lithiasis also affected the former Soviet republics, from an average of 53/100,000 inhabitants in the USSR in 1980, in 2005 the incidence was 103/10,000 inhabitants in Belarus, 256/10,000 inhabitants in Tajikistan, and 658/10,000 inhabitants in Ukraine (4). We can say that this is also true in our country because in the last 30 years we have witnessed a radical change in the lifestyle of young people in Romania. Thus, the diet tends to copy the western one, rich in animal protein, salt and low in vegetable fiber. Fast food restaurants have seen an explosive expansion in our country. These foods are "seasoned" in abundance with carbonated beverages. If we consider the degree of the sedentary lifestyle of the young population, we will be able to draw a favorable picture of the appearance of urinary stones. The appearance of nephrolithi-

asis is not only the result of the presence of certain favorable factors (salt, animal proteins, refined carbohydrates, etc.) in these foods but also indirectly through changes in the body such as the development of diabetes and in some cases metabolic syndrome.

Unfortunately, one of the characteristics of urinary stones that makes it necessary especially in young patients for strategies of etiological evaluation, prophylaxis and metaphylaxis is the potential for recurrence. The relapse rate is variable depending on the geographical area, lifestyle, eating habits, etc. In a meta-analysis conducted in the late 1980s by Uribarri *et al.,* a "cumulative natural recurrence rate" of 14% at 1 year, 35% at 5 years, and 52% at 10 years were found (5). 25 years later, Rule *et al*. Found a recurrence rate in Olmsted County, Minnesota, the USA of 11% at 2 years, 20% at 5 years, 31% at 10 years, and 39% at 15 years (6). According to Osther, lithiasis has a high potential for recurrence among Europeans. According to the author, in general, when surveyed, 60% of German or Danish patients will report a single lithiasis episode, 18% two, 10% three, 2% four, and the rest more than four episodes. The chemical composition of the stones seems to play a very important role in recurrence (7). Thus, Levi *et al*., in a group of approximately 450 patients, found a 3-year recurrence rate of 24%, but patients who had uric acid or struvite stones were 2.4 times or 1.9 times higher show greater recurrence than those that formed calcium oxalate stones (8). Fortunately, knowing the potential for reversal by implementing prophylactic measures, according to Borghi *et al*., the recurrence rate can be reduced by up to 50% (9).

The purpose of clinical and metabolic evaluation of lithiasis patients is to prevent lithiasis recurrence, to stop the growth of existing stones and to reduce the need for surgery. Although it is a disease that mainly affects relatively young people, with an increasing incidence and prevalence all over the world, the investigation of the etiology, from the point of view of some authors, still has a controversial utility.

In terms of cost-effectiveness, Chandhoke suggested that in patients with the first episode of lithiasis, metabolic assessment is not warranted (10). The author indicated that only at a rate of 0.3-4 lithiasis episodes/year metabolic assessment and treatment is equivalent to the management of lithiasis recurrence. On the other hand, according to Chapple *et al.,* In patients with a first lithiasis episode, the recurrence rate after conservative treatment is 0.07 stones/patient/year. Because conservative treatment is at least as expensive for those with lithiasis recurrence, first-time patients should not receive special treatment (11). Therefore, it could be argued that while 24-hour urine analysis may not be considered a practical and sometimes uninformative tool, according to Hill *et al.,* It is a personalized impulse of the diagnostic pathway that will determine consideration of subsequent genetic investigations (12). The authors cite the situation where a 24-hour urine test or a cystine urine test (cystine/creatinine ratio) is a valid screening test for lithic patients to identify cystinuria. Moreover, the authors consider that even the analysis of the composition of the calculation provides only one temporary reference and can be misleading. For example, it has been found that some patients with cystinuria form calcium oxalate stones before the formation/identific-

ation of cysteine.

Most authors agree that in the case of patients on the first presentation but who may be included in a high-risk group, metabolic assessment is necessary. These high-risk groups include hereditary history, intestinal disorders, and chronic diarrhea, urinary tract infections, gout, osteoporosis, or bone fractures. To this could be added patients who are highly motivated to change their eating and health habits, those with single kidneys, those with multiple stones, or subjects with multiple and severe comorbidities to whom possible urological surgery would be at risk. grown. Although some authors argue that patients with uric acid, cystine, and struvite stones require metabolic evaluation, according to Chapple *et al*., These categories of patients were used to identify those who did not need metabolic evaluation (11). A special category of patients for whom the metabolic assessment is warranted is those whose lithiasis is difficult to treat, those with single kidney disease, and those with nephrocalcinosis. According to Chapple *et al.,* Children with urinary stones should be evaluated metabolically (11). Adolescents with lithiasis have the same risk of metabolic disorders as adults. The risk of ureterohydronephrosis, urinary tract infections, and an increased need for surgery further support metabolic assessment in children and adolescents.

The European Urology Association (EAU) guidelines recommend that after stone passage, every patient should be assigned to a low- or high-risk group for stone formation. To classify the patient, we need to perform the stone analysis through X-ray diffraction or infrared spectroscopy and metabolism-related laboratory analysis like 24-hour urinalysis (13). However, for some patients, 24-hour urine collection may not be an easy task, and in the end, compliance may be low. We, therefore, wonder if patients really want to be metabolically evaluated. A high level of interest for first-time patients is likely due to the severity of pain associated with renal colic and significant time lost from work or other activities. Once the patient's symptoms disappear, he is increasingly likely to lose interest in metabolic assessment. Given these disadvantages, we ask ourselves if one 24-hour urine sample is enough. According to Williams et al. one sample may not be enough, the authors recommend that at least two 24-h urine analyses for initial evaluation of stone patients. One collection should be made on a workday and the other should be made during a non-workday (14).

Once it is established that the patient needs a 24-hour urine test, the question naturally arises: when is the best time to affect this investigation? At the first presentation, the acute complications of lithiasis should be treated first and the symptoms that caused the patient to see a doctor should be alleviated. After clearing the pyeloureteral system, the etiological treatment will be applied: expulsion or surgical treatment. Once these goals are met, Chapple *et al.* Recommend that metabolic evaluation be performed at least one month after removal of the stone to allow the body to return to its original status (11). By taking blood or urine during the acute lithiasis episode (obstruction, infection, renal colic) irrelevant information is obtained. However, this opinion is not shared by Chandhoke, who considers that the patient doesn't need to be stone-free at the time of evaluation, the only precondition is

the absence of macroscopic hematuria and renal obstruction (15). In practical terms, 2-4 weeks wait after ESWL or another endourological procedure is usually sufficient before collecting urine specimens for metabolic analysis.

Evaluation of patients with an isolated lithiasis episode is still a matter of debate. Because they noted low morbidity associated with the first episode of lithiasis and a relatively high incidence of side effects of drug metaphylaxis, some authors do not recommend evaluating this category of patients. However, it has been shown that patients with an isolated lithiasis episode may have the same metabolic disorders as those with recurrent lithiasis, so they have the same risk of recurrence as those with multiple histories of lithiasis.

In addition to a detailed history, patients presenting for the first time with urinary stones should have a urinalysis and urine culture, ionogram, calcium, uricemia, to detect renal tubular acidosis, hyperparathyroidism, or gout, and 24-hour urine analysis. They should also be evaluated for imaging for outstanding lithiasis and possibly urinary tract malformations.

The chemical composition of stones has a crucial role in therapeutic conduct. In this way, patients who are candidates for lytic treatment and those who will undergo surgery can be selected. It can also guide treatment for metaphylaxis of lithiasis recurrence. There are currently two methods of analysis commonly used for stone analysis, namely X-ray powder diffraction crystallography (XRD) and Fourier transform infrared spectroscopy (FTIR). The classical technique of chemical analysis, the so-called “wet analysis”, is no longer recommended by the EAU due to its poor reliability. These two methods of analysis differentiate the crystalline composition based either on the uniqueness of the crystalline structures or the subtle energetic differences associated with the movement of atoms in chemical bonds found in the various stone components. The first results of the application of FTIR microscopy (mFTIR) to the urinary crystals of calculating stones were published in 1991 by Daudon *et al.* In subsequent research, the same group expanded studies combining FTIR with a pellet of potassium bromide (KBr) instead of FTIR microscopy. Combining the spectral results for urinary sediments and kidney stones obtained by the KBr pellet technique with the results of optical sediment microscopy, the authors found a 97.3% correlation between the type of calculation and the type of crystals in urine sediments. These studies have been restricted because urinary crystals can be investigated by the KBr pellet technique only when a significant number of precipitated crystals (16).

We consider that the most comprehensive and at the same time precise synthesis of the research in the field of the biochemical composition of lithiasis was made by Daudon *et al*.

This classification, which favors an easy communication between biochemists, nutritionists, and urologists, brings into question the following possible etiopathogenic situations (tab. I).

The morphological types of stones in urinary lithiasis are divided into Calcium and Non-calcium. Calcium-type stones are made up of either oxalate or calcium phosphate. Non-calcium urolithiasis is due to accumulations of uric acid, infections, or genetic causes (cystine).

TABLE I

Calcic		Non-calcic		Calcic		Aminoacids
Type I	**Type II**	**Type III**	**Type IV c**	**Type IV d**	**Type IV a**	**Type V**
Calcium oxalate monohydrate	Calcium oxalate dihydrate	Uric acid	Struvite (ammonium magnesium phosphate)	Brushite (calcium hydrogen phosphate dihydrate)	Carbonate apatite (calcium phosphate)	Cystine (L-cystine)
-Hyperoxaluria -Calcium/oxalate low ratio -Sponge kidney -Randall plaques -Urinary stasis	-Hypercalciuria -Calcium / oxalate increased ratio -Randall plaques	Hyperuricosuria -Low urinary PH -Insulin resistance / Type 2 diabetes -Urinary stasis	-Infections related to the production of urea by microorganisms -Presence of Struvite -a sign of an infection with urea splitting bacteria	-Hypercalciuria -Primary hyperthyroidism	-Hypercalciuria -Urinary infections -Sponge kidney -Renal tubular acidosis and Sjogren Syndrome	Cystinuria (autosomal-recessive disease)

The morphological types of stones in urinary lithiasis are divided into Calcium and Non-calcium. Calcium-type stones are made up of either oxalate or calcium phosphate. Non-calcium urolithiasis is due to accumulations of uric acid, infections, or genetic causes (cystine).

Calcium lithiasis

- Type I - calcium oxalate monohydrate occurs as a result of: hyperoxaluria, low calcium/oxalate ratio, sponge kidney, Randall plates formation, urinary stasis;
- Type II - calcium oxalate dihydrate, due to: hypercalciuria, increased calcium/oxalate ratio, Randall plaques formation;
- Type IV d - brushite (dicalcium hydric phosphate) - occurs in: hypercalciuria, primary hyperthyroidism;
- Type IV a - apatite carbonate (calcium phosphate): hypercalciuria, urinary infections, sponge kidney, renal tubular acidosis, Sjogren Syndrome.

Non-calcium lithiasis

- Type III - uric acid - occurs by precipitation of uric acid crystals in the following situations: hyperuricosuria, low urinary pH, insulin resistance / type 2 diabetes, urinary stasis, benign prostatic hyperplasia;
- Type IV c - struvite (ammonia-magnesium phosphate) is due to: urea splitting micro-organisms that cause urinary tract infections, the presence of struvite in the urine - a sign of urease-producing bacteria involved in urinary tract infections;
- Type V - cystine (L-cystine) - caused by autosomal recessive genetic disease that causes cystinuria.

Luckily, the progress made in determining the composition has helped us to be in the position to intervene decisively in cor-

recting important factors that cause the recurrence of kidney stones. We must mention the correction of urinary pH first, knowing that 76.3% of kidney stones are formed in either alkaline or acidic pH (17). This therapy must be integrated with the specific dietary guidelines for each biochemical type.

Uric acid lithiasis, which is formed in acid urinary pH, benefits from chemolysis, alkalinization being performed under control with preparations containing K and Mg citrate (e.g., ALKASOLV® or ALKALIUM®). Daily monitoring of urinary pH causes must lead to an ideal therapeutic pH of 6.8- 7.0.

Phosphate lithiasis that occurs at an alkaline pH may benefit from effective metaphylaxis with drugs containing L-methionine, which manage to acidify the urine (e.g., ACIDURIN®). In this way, careful monitoring of pH is the key to determining the right dose for the intended purpose (ideal treatment should lead to a urinary pH of 5.5-5.8). The medication will accompany an adequate diet and abundant consumption of water or mineral water (recommended for each biochemical type).

In conclusion, the correct metaphylaxis cannot be done without knowing the metabolic disorders that led to the appearance of the stones and without knowing the precise composition of the stones, performed by Fourier transform infrared spectroscopy (FTIR). Unfortunately, in about one to five patients the lithiasis recurrence has a different composition, which requires careful long-term monitoring and, in our opinion, a complex both morphological and spectroscopic analyze for each recurrent stone.

NEWS

SIGNIFICANCE OF NON-HLA ANTIBODIES IN LOW-RISK KIDNEY TRANSPLANT RECIPENTS

This prospective study included total 94 recipients among 201 consecutive recipients who underwent an ABO-compatible living donor kidney transplant (LDKT). Angiotensin II type 1 receptor antibodies (anti-AT1R) and anti-endothelial cell antibodies (AECA) were measured before, during and after LDKT. The prevalence of acute rejection (AR) within 12 months post-transplant did not differ significantly based on anti-AT1R levels and AECA results. However, when a cut-off value of 11.5 U/mL was applied, it independently predicted a higher risk for AR. AECA (+) recipients had a higher risk for AR or microvascular inflammation (MVI) only during the follow-up period and also showed a rapid increase in creatinine and decrease in eGFR at approximately three months; after this point, they showed persistently higher creatinine and lower eGFR until 20 months. Pre-transplant anti-AT1R level was a significant risk factor for the development of AR, while AECA status was associated with impaired renal function regardless of AR. (Shinae Yu, *et al.*, Pre-Transplant Angiotensin II Type 1 Receptor Antibodies and Anti-Endothelial Cell Antibodies Predict Graft Function and Allograft Rejection in a Low-Risk Kidney Transplantation Setting. *Ann Lab Med* 2020; 40(5): 398-408).

EDITORIAL

DERMATOVENEROLOGY CLINIC OF "SF. SPIRIDON" HOSPITAL IAȘI AT 140 YEARS

The Dermatovenerology Clinic of the Saint Spiridon Hospital Iași was established in 1849 by G. Cuciureanu as a Section for Syphilis of the hospital, and in 1882 it became a Dermatological Clinic. The first lecture in dermatology was given by Dr. Gh. Iuliano - May 20, 1882, and he taught until 01.02.1883. For almost 20 years, until 1900, the filling of the chair was done by professors from other departments: Prof. V. Negel, Prof. Russ Jr., Prof. Gh. Bogdan, and in the period 1900-1901 this activity of was assigned by Dr. I. Ţăranu, secondary doctor of the department. In 1901, Dr. Gh. Demetriade managed to obtain the position of full professor, following the organized competition.

Prof. Gh. Demetriade (1860-1923)

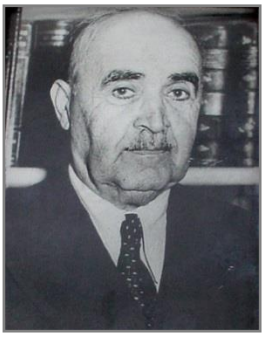
Prof. Gh. Demetriade (1860-1923), a student of Prof. Petrini-Galaţi, trained in Paris and Berlin: he was concerned with teaching, organizing the museum of molds and the library (hires as molds technicians the medical student E. Mironescu, then I. Rotaru). He was concerned with scientific research, introducing ultramicroscopy and serodiagnosis for syphilis. He was in charge of increasing the number of beds of the clinic, consultations and outpatient treatments for syphilis, soft canker, etc.

Prof. Dr. Eugen Mironescu (1883-1939)

From July 1923, Prof. Dr. Eugen Mironescu (1883-1939), occupies the position of head of department by transfer from pharmacology, contributing to the further development of education, renovating and modernizing the clinic, expanding the library and the mold museum (1).

I.I. Mironescu, as he signed as author and writer, is the pseudonym of professor and doctor Eugen I. Mironescu. He studied medicine in Berlin; he was the head of the Dermatology Clinic and a professor at the Faculty of Medicine in Iași; published valuable scientific papers; held numerous popularization conferences in the country; he ran a SPA and built a sanatorium out of his own money; initiated a medical publica-

tion; set up an antiparasitic treatment service and an office for treatment with therapeutic baths and free medication; supported medical students; he was a respected medical educator, gave numerous public lectures on family hygiene and the prevention of venereal diseases; led an intense anti-venereal campaign, writing and printing numerous brochures with explanations and advice for the population. I.I. Mironescu was a doctor on the front lines of the Balkan War; he was involved in stopping epidemics in the Great War - for his activity he was later decorated with high distinctions of the Romanian and French State (2, 3).



Prof. Dr. Gheorghe Năstase (1887-1975)

Since December 1st,1942, Prof. Dr. Gheorghe Năstase (1887-1975) is a full professor, head of department till 1956, consulting professor till 1962. He developed courses in dermato-syphilography, publishes under his editorship the *Treaty on dermato-venereology* unique in the country. He was a good organizer, renowned dermatologist, elite researcher (over 300 scientific papers, participation in congresses, description of new entities, formulation of etiological hypotheses, studies in mycoses, pyoderma, cutaneous tuberculosis, occupational dermatoses, skin cancer) (4, 5).

Prof. Dr. Doc. Virgil Costea (1906-1990)

Prof. Dr. doc. Virgil Costea (1906-1990) goes through the usual stages in his teaching activity, being the head of the discipline since 1961. He collaborates in writing the dermatology course of Prof. Gh. Năstase and writes a dermatology course adapted for pediatrics. He became a specialist in dermato-venereology and then in hygiene, following the courses he took; is in charge of organizing the dermato-venereology clinic and network in Iași and the Iași Region. Introduces for the first time in the world the treatment with corticosteroids in inflammatory trichophytosis, together with griseofulvin, obtaining a prompt reduction of the inflammatory phenomena and a faster healing (6).

Prof. Dr. Doc. Mircea Munteanu (1913-2002)

Prof. Dr. Doc. Mircea Munteanu (1913-2002) went through the usual stages in his teaching activity, becoming a professor since 1967. In his research activity he has over 300 scientific papers (more than 200 published); participates in scientific meetings in the country and abroad, in the organization of the Conference "Gh. Năstase Days" in Iasi. Obtain a certificate of innovator for an antiparasitic, antimicrobial and fungicidal ointment; He is a contributor to the International Contact Dermatosis Research Group and the International Psoriasis Research Group. He contributes to the organization of the Centenary of U.M.Ph. (1979) and the Centenary of the Dermatological Clinic (1982), of symposia to celebrate 100 years since the birth of Prof. Dr. E. I. Mironescu, then 100 years since the birth of Prof. Dr. Gh. Năstase (6).

Prof. Dr. Al. Dobrescu (1923-1999)

Prof. Dr. Al. Dobrescu (1923-1999) went through the usual stages in teaching, becoming a teacher in 1991. He is the head of the discipline and Dermatology Clinic from 1980 to 1994, when he became a consulting professor; He organizes together with Prof. M. Munteanu the Centenary of the Dermatological Clinic, of the Commemoration of the 100th anniversary of the birth of Prof. E. I. Mironescu and Prof. Gh. Năstase; Organizes and participates in the organization of the Conference "Gh. Nastase Days", in Iasi (6).

In his medical activity, he was concerned with organizing the activity in the new headquarters in the Tătărași neighborhood, in order to ensure the specialized assistance in accordance with the requirements of the Ministry of Health and Family.

Prof. Dr. Zenaida Petrescu has been the head of the Discipline and Clinic since 1993. He collaborated in the realization of a "Course in Semiology and Medical Pathology, Endocrinology, Dermatology and Phtiziology", Balan M., Zbranca E., Petrescu Zenaida, Mihăescu T. (1987), the treatise "Human Physiology" (Skin Physiology Chapter) edited by I. Hăulică (1996), the volume "Family Planning" (Chapter Sexually Transmitted Diseases) - Florentina Pricop and collaborators (1997); she organized the Dermatology Conference "Gh. Nastase Days". She obtained a certificate of innovator for a drug used in the treatment of pyoderma; training from a professional point of view under the guidance of the masters of the Clinic (Prof. Dr. Gh. Năstase, Prof. Dr. Doc. V. Costea, Prof. Dr. Doc. M. Munteanu, Prof. Dr. Al. Dobrescu) and advanced training in the service of Prof. J. Civatte, Prof. S. Belaïch, Prof. L. Dubertret, Prof. Camille Frances - Paris.

Currently, the Dermatovenerology Clinic of "Sf. Spiridon" Hospital is the largest in Iași and in the country with 40 beds and has been run since 2008 by Prof. Dr. Laura Gheucă Solovăstru, primary dermatologist, Doctor of Medical Sciences and coordinator of teaching activity, Dermatology Discipline, Faculty of Medicine, "Grigore T. Popa" University of Medicine and Pharmacy from Iasi. She was Vice Dean of the Faculty of Medicine from 2009 to 2012. She organizes the Dermatology Conference

"Gh. Năstase Days", now in its 28th edition, being the President and Executive Director of the Conference. She is the Director of the Department of Medical Specialties (III), Faculty of Medicine, "Grigore T. Popa" University of Medicine and Pharmacy from Iasi and member of the University Senate.

In 2015, the headquarters of the Dermatological Clinic of the "Sf. Spiridon" Iași County Clinical Emergency Hospital returned from Tătărași in the center, to the Hospital Ambulatory where it occupies the right wing of the 3rd and 4th floors, with a practical work room for medical students in the basement of the building. and two consulting rooms on the 1st floor.

Today, ten dermatovenerologists work in the Dermatology Clinic together with fifteen nurses and ten caregivers. The department has a medical profile and a consistent surgical component, with great addressability. It ensures the diagnosis and treatment for the dermatological pathology of the patients from Iași, as well as from the counties from the northeast region of the country. The population served is numerous, and the medical act is characterized by a high professional, scientific and ethical responsibility.

The Dermatovenerology department also carries out clinical activity within a national program: *The program dedicated to patients with Bullous Epidermolysis*, carried out in collaboration with the Ministry of Health under the coordination of Prof. Dr. Laura Gheucă Solovăstru.

The clinic operates in an ANMCS accredited hospital - ISO certified - with high addressability. The investigations performed in the Clinic are processed in modern internal laboratories RENAR accredited. The activity takes place in a completely sanitized and modernized new space, ensuring superior hotel conditions to many Dermatovenerology clinics in the country. The clinic benefits from human resources with recognized responsibility and professional ethics, in assuming and carrying out professional tasks, helped by specialized equipment for services in the field of dermatology. The medical team consists of young physicians, academics, residents and registered nurses.

Dan Vâță, M.D., Ph.D.,
Lecturer of Dermatology

COMORBIDITIES IN PATIENTS WITH POST-OPERATIVE MENINGITIS IN NEUROSURGERY (Abstract): Meningitis is a serious condition that affects the central nervous system and can be caused by bacterial, viral, or fungal infection . Postoperative meningitis is a post procedural complication and disorder of the nervous system. **Material and methods**: We performed a retrospective study between 2016 and 2019 including 627 patients who underwent neurosurgical interventions. Of these, 32 presented postoperative meningitis being admitted between 2016 and 2019 to the "Sf. Parascheva" Clinical Hospital of Infectious Diseases, Iasi, in order to assess the impact of comorbidities among these patients. **Results**: From 24 patients with comorbidities, we evaluated a percentage of 45.83% patients with ischemic heart disease. We identified a number of 15 patients (62.5%) with arterial hypertension, which demonstrates the high prevalence of vascular diseases among these cases. Also, we found 4 cases with metabolic disorders which means 16.66% from all the patients with associated pathology. On the other hand, we analyzed the prevalence of other important associated comorbidities which can increase the mortality and morbidity associated risk. **Conclusions**: The impact of multiple comorbidities on the management and evolution of infectious diseases, especially in postoperative meningitis, is complex and needs collaboration with colleagues from all the specialties involved. **Keywords**: POST-OPERATIVE MENINGITIS, COMORBIDITIES, NEUROSURGICAL COMPLICATION.

Meningitis is a serious condition that affects the central nervous system. It is an inflammation of the meninges, which is the membrane that surrounds both the brain and the spinal cord. Meningitis can be caused by bacterial, viral, or fungal infection (1). Postoperative meningitis is a post procedural complication and disorder of the nervous system. Measurement of cerebrospinal fluid (CSF) cytokine and lactate levels in conjunction with meningitis diagnostic procedures may contribute to the early and precise detection of post-neurosurgical meningitis. Measuring CSF lactate is affordable and cost-effective, especially in patients who have just had

neurosurgery (2). Molecular techniques, such as polymerase chain reactions that target 16S ribosomal RNA, can help with diagnosis, direct therapy, and pinpoint microbes that can't be cultivated. Recent studies recommends combining approaches for patients with bacterial meningitis suspected following neurosurgery, particularly when the culture is negative (3). A recent study showed *Klebsiella pneumoniae* (25.6%) was the most prevalent isolate in patients with community-acquired meningitis, followed by *Streptococcus pneumoniae* (18.6%) and *Listeria monocytogenes* (11.6%). Ceftriaxone, cefepime, and meropenem each had susceptibility rates of 85.7%, 81.3%, and 100% for *K. pneumoniae*, correspondingly. Patients who had meningitis while receiving neurological treatment most frequently had coagulase-negative staphylococci (28.0%), followed by *Staphylococcus aureus* (16.1%) and *Enterobacter* spp (13.6%). About 39% of patients experienced neurological problems, and 14.8% of patients died within three months. After controlling for confounders, older age, neurological issues, and an initial Glasgow coma rating of less than eight were all strongly linked to a poor outcome (4). It was concluded that intrathecal administration of antibiotics such as gentamicin, amikacin, and colistin with low blood-brain barrier transition in intravenous treatment will enhance survival in post neurosurgical meningitis caused on by carbapenem-resistant agents. In order to prevent nosocomial meningitis, intrathecal antibiotic treatment should be considered standard practice (5). In a sample group of patients with post-neurosurgical meningitis, diabetes mellitus (15.4%), chronic lung disease (12.8%), renal disease (6.0%), and cerebrovascular disorders (5.8%) were the most prevalent comorbidities. There were 1,120 (4.2%) cases of AIDS and HIV infection (6). Among patients with postoperative meningitis, the presence of comorbidities has been shown to be an important risk factor as in the other types of bacterial meningitis. According to research on patients with meningococcal meningitis over a forty-year period, there is a 2- to 40-fold higher chance of developing kidney disease, immunological problems, liver disease, cancer, and organ transplantation (7). According to cohort research from Spain, people with diabetes mellitus with bacterial meningitis tend to be older, have more comorbid conditions, and have higher fatality rates. The most common infections are *S. pneumoniae* and *Listeria monocytogenes*, with *L. monocytogenes* being more prevalent. *Neisseria meningitidis* is much less common in diabetics than in non-diabetics (8).

MATERIAL AND METHODS

We performed a retrospective study between 2016 and 2019 including 627 patients who underwent neurosurgical interventions. Of these, 32 presented postoperative meningitis being admitted between 2016 and 2019 to the “Sf. Parascheva” Clinical Hospital of Infectious Diseases, Iasi, in order to assess the impact of comorbidities among these patients. Statistical analysis was performed in *SPSS 27.0* using Pearson Chi-squared test.

RESULTS

The average length of hospital stay was 20.37 days. There were 8 patients who also associated sepsis. We also evaluated the length of intervention: 10 cases with more than 180 minutes, 10 cases with more than 240 minutes and 12 cases with more than 280 minutes (fig.1).

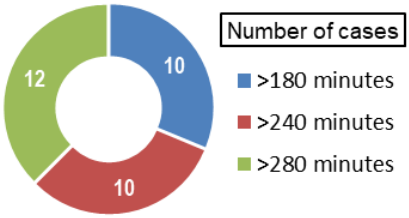

Fig. 1. Distribution of cases by intervention length

From a total of 32 cases with postoperative meningitis, 8 (25%) were complicated with sepsis. During hospitalization, we also assessed qSOFA score and Glasgow Coma Scale (GCS) (tab. I).

The patients management was individualized according to the specific profile of their comorbidities. From all the patients included in this study, 75 % had comorbidities (fig. 2).

From 24 patients with comorbidities, we evaluated a percentage of 45.83% patients with ischemic heart disease. Also, we identified a number of 15 patients (62.5%) with arterial hypertension, which demonstrates the high prevalence of vascular diseases among these cases (fig. 3).

From this point of view, we can also suggest that the double association ischemic heart disease-arterial hypertension was prevalent in elderly patients (7 patients from a total of 24 with comorbidities), with a median age of 63 years old (fig. 4).

We identified 4 cases with metabolic disorders which means 16.60% from all the patients with associated pathology (fig. 5).

On the other hand, we analyzed the prevalence of other important associated comorbidities which can increase the mortality and morbidity associated risk. We calculated the same percentage for pulmonary disorders and neoplasia (20.88%), both of them with important repercussion in patient's evolution and prognosis (fig. 6).

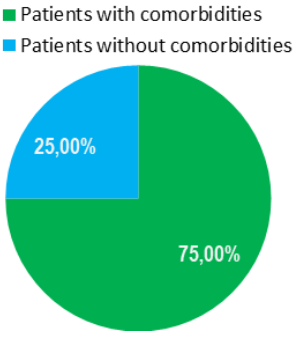

Fig. 2. Percentage of patients with comorbidities

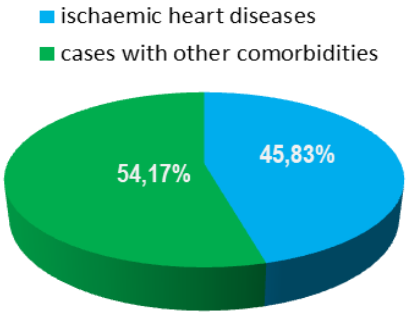

Fig. 3. Percentage of patients with ischemic heart disease from all cases with comorbidities

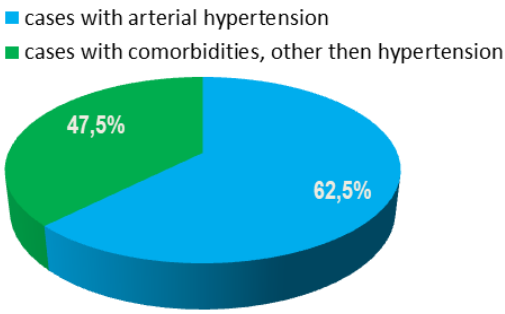

Fig. 4. Percentage of patients with arterial hypertension from all cases with comorbidities

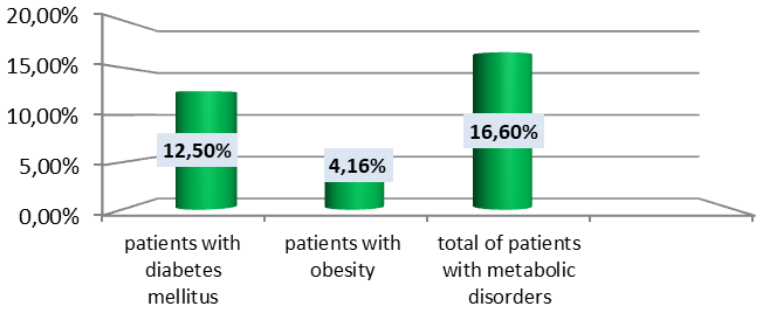

Fig. 5. Percentage of patients with metabolic disorders from all patients with comorbidities

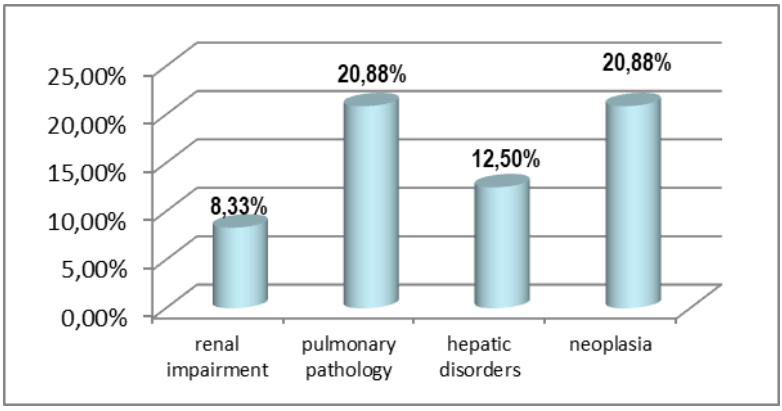

Fig. 6. Percentage of cases with other comorbidities than metabolic and cardio vascular

From the total number of cases with associated comorbidities 6 patients (25% from all cases with comorbidities) presented 3 or more associated pathology (fig. 7).

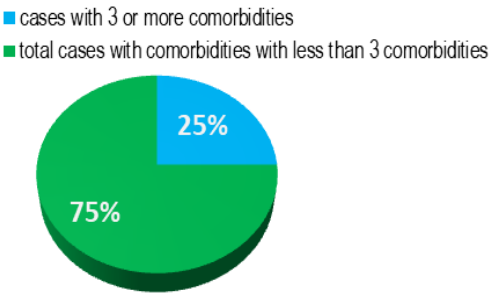

Fig. 7. Percentage of patients with 3 or more comorbidities from all patients with associated pathology

Taking into account the group of 28 adult patients who had a favorable evolution, in which no mortality was recorded, we evaluated the relationship between patients' age groups, the relationship between GCS score, as well as the relationship between systemic pathology and the prevalence of postoperative meningitis.

Statistical analysis. Table II shows the relation between patients' age groups and the prevalence of post-operative meningitis (POPM).

TABLE II.

Pearson Chi-squared test for prevalence of POPM related to gender

Pearson Chi-squared = 0.252 p = 0.616		POPM				Total	
		POPM+		POPM-			
		N	%	N	%	N	%
GENDER	F	10	35.7%	238	40.5%	248	40,3%
	M	18	64.3%	350	59.5%	368	59,7%
Total		28	100.0%	588	100.0%	616	100.0%

In patients with POPM the share of men is higher (64.3%, compared to 59.5% in males' group without POPM), but without statistical significance. In patients with POPM the share of patients with age <=60 years is significantly higher (67.9%) comparing with the same share in patients without POPM (2.4%) (tab. III).

TABLE III.

Pearson Chi-squared test for prevalence of POPM related to age group (<60 *vs.* ≥60)

Pearson Chi-squared = 225.996 p = 0.000** / OR = 86.556; 95%CI OR = 33.341 ÷ 224.702		POPM				Total	
		POPM+		POPM-			
		N	%	N	%	N	%
AGE GROUP	<= 60 years	19	67.9%	14	2.4%	33	5,4%
	> 60 years	9	32.1%	574	97.6%	583	94,6%
Total		28	100.0%	588	100.0%	616	100.0%

Table IV shows the relation between patients' GCS score and the prevalence of post-operative meningitis. In patients with POPM the share is significantly higher for patients with GCS 12-15 (53.6%) comparing to patients with GCS scores 10-11 (25%) and <10 (21.4%). This discrepancy is bigger in patients without POPM, among which the share of patients with GCS 12-15 is 81.0%, comparing to patients with GCS scores 10-11 (8.3%) and <10 (10.7%).

TABLE IV.

Pearson Chi-squared test for prevalence of POPM related to age group (<60 *vs.* ≥60)

Pearson Chi-squared = 13.420 p = 0.001**		POPM				Total	
		POPM+		POPM-			
		N	%	N	%	N	%
GCS	<10	6	21.4%	63	10.7%	69	11,2%
	10-11	7	25.0%	49	8.3%	56	9,1%
	12-15	15	53.6%	476	81.0%	491	79,7%
Total		28	100.0%	588	100.0%	616	100.0%

Table V shows the relation between patients' systemic pathology and the prevalence of post-operative meningitis. The share of patients with lung diseases is significantly bigger among those with POPM compared with those without POPM (21.4% *vs.* 6%); the same phenomenon is reported in the case of patients with liver diseases (10.7% from those with POPM *vs.* 0% from those without POPM).

TABLE V.

Pearson Chi-squared test for prevalence of POPM related to systemic pathology

In which concerns the incidence of other systemic diseases, Pearson Chi-squared test did not find statistically significant differences between patients with POPM and patients without POPM.

CONCLUSIONS

The study confirmed the impact of comorbidities on the evolution of patients with postoperative meningitis. In our cohort it was a fatality of 12.5 % and 28 cases with a positive evolution. Deaths were reported predominantly among men (3 cases) aged 33 to 77 years. All the cases had associated pathologies and we observed the presence of an association of

cardiovascular and metabolic comorbidities. The management of all patients was daily revised and optimized with multidisciplinary approach which was individualized for every single case. The impact of multiple comorbidities on the management and evolution of infectious diseases, especially in postoperative meningitis, is complex and needs collaboration with colleagues from all the specialties involved. The positive evolution of postoperative meningitis needs an early diagnosis and a good partnership with other specialties with daily adaptive treatment depending on the particularities of the patient.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

EDITORIAL

SMALL DICTIONARY AT THE IT / MEDICINE INTERFACE

The immense and continuous progress that Information Technology (IT) has had in recent years and continues to have, inevitably, a major impact on the medical field as well. The benefit it can bring to medicine and the patient is indisputable, but it depends equally on the understanding on that one hand of the needs that the medical sector has to be solved by IT techniques by IT specialists. On the other hand, the interpretation of the data resulting from the application of IT techniques by IT professionals and doctors is for the final benefit of the patient. That is the existence of a common language that allows communication between these two domains. New terms appeared and continue to appear, most often neologisms from the English language. We proposed to bring together in this editorial a series of terms widely used at the IT/medicine interface, with the aim of facilitating communication in research carried out in mixed collectives. We did not intend to exhaust the terms that would be necessary to define, the scope of the subject would have exceeded the scope of an editorial. We only hope that this editorial will be a good starting point for other materials of this kind.

A: Artificial Intelligence (**AI**) - a general term used to describe algorithms designed for recognition, problem solving and reasoning, generally associated with human intelligence, essentially imitating some aspects of intelligent human behavior (1). The term artificial intelligence first appeared in an application for a 6-wk workshop entitled Dartmouth Summer Research Project on Artificial Intelligence at Dartmouth College in Hanover, New Hampshire, and is often defined as "intelligence demonstrated by machines, in contrast to the natural intelligence displayed by humans and animals" (2). Since its first appearance, the term has undergone a constant redefinition against the background of what is technically feasible. On the one hand, the definition per se is already vague, because the partial term intelligence is not itself well defined. On the other hand, it depends directly on human perception and evaluation, which change constantly (3).

Artificial Neural Network (**ANN**) - a subset of AI; in medical imaging, an ANN is an image analysis algorithm composed of layers of connected nodes that simulate the neuronal connections of the human brain (1).

B: Big Data - term defined based on the 4 Vs: variety, velocity, volume, and variety. Traditionally, data are considered big when they rank high on several of these dimensions (4).

C: Classification - term use in IT to define a process related to categorization, the process in which ideas and objects are recognized, differentiated and understood (5).

Computer-Aided Design (CAD) software - the use of computers (or workstations) to aid in the creation, modification, analysis, or optimization of a design. Today, CAD tools are being employed to bring about exciting new advances in biological and medical progress, as they are tackling challenges that in the past decades

could have only been dreamed of being conquered (6).

Computed Tomography (CT) - *in vivo* structural imaging acquisition technique, giving high resolution images. Usually, CT refer to the technique used in Radiology, where X-radiation is the physical agent, and the image is the expression of the degree of attenuation of this radiation in relation to the tissue density. A narrow beam of x-rays is aimed at a patient and quickly rotated around the body, producing signals that are processed by the machine's computer to generate cross-sectional images, or "slices". But, in fact, referring to the acquisition modality, there are also CT with other physical agents, as in SPECT (with gamma radiation) (7).

D: Decision Tree - represent a computerized decision support tool that uses a tree-like model of decisions and their possible consequences, including chance event outcomes, resource costs, and utility. It is one way to display an algorithm that only contains conditional control statements. Decision trees are commonly used in operations research, specifically in decision analysis, to help identify a strategy most likely to reach a goal but are also a popular tool in ML (6).

Deep Learning (DL) - a sub-type of ML that adds a number of processing layers (depth) to detect complex features in an image typical of a certain type of ANN (1).

Digital Imaging and Communications in Medicine (**DICOM**) - the international standard to transmit, store, retrieve, print, process, and display medical imaging information (8).

Digital Health - refer to the technologies use computing platforms, connectivity, software, and sensors for health care and related uses. These technologies span a wide range of uses, from applications in general wellness to applications as a medical device. They include technologies intended for use as a medical product, in a medical product, as companion diagnostics, or as an adjunct to other medical products (devices, drugs, and biologics). They may also be used to develop or study medical products (9).

Digital Technology - encompasses digital devices, systems, and resources that help create, store, and manage data (10).

E: e-health - refer to the use of information and communication technology to support health and healthcare. Three major predicted areas of disruption are telemedicine, smartphone Apps, and wearable sensors. Increasingly, citizens are using digital technologies to support their own health and healthcare decision making (11).

F: Fused image - image that is the result of superposing a functional image (image that is related to the function/phenotype characteristics of the tissue) with a structural one (image that depend only on the structural characteristics of the tissue, but not directly on the nature/phenotype markers of the cells). Give the possibility to accurate localize a specifical functional image. It represents, nowadays, the most advanced part of imaging, with clear advantages for the surgical approach of tumoral processes. Examples: SPECT-CT, PET-CT, PET-MRI (12).

G: Gamma camera - detection device in nuclear medicine, for *in vivo* imaging. Detects the gamma radiation emitted by the radioisotope within the specifically administered radiotracer (technique known as scintigraphy). Depending on the type of the device and the type of radioisotope/ radiotracer used or acquisition technique, can be distinguished SPECT, PET, whole body or

planar imaging techniques. Also called **scintillation camera** or **Anger camera** (7).

I: Image processing - The action of analyzing images acquired *in vivo* or *in vitro*, for the purpose of qualitative and quantitative evaluation and imaging diagnosis, using computer software, in order to get an enhanced image or to extract some useful information from it. It is a type of signal processing in which input is an image and output may be image or characteristics/features associated with that image. Image processing depends on the computer's software and IT capabilities, evolving along with them (13).

Information Technology (IT) - the use of computers to create, process, store, retrieve, and exchange all kinds of data and information (8).

Internet of Things (IoT) - a network of physical objects that are fitted with sensors, software and other technologies. Connected to the Internet, these "things" are able to exchange real time data with other connected devices and systems over networks. These connected devices combine with automated systems to gather IoT data that can be analyzed to assist with tasks or learn how to improve a process (14).

M: Machine Learning (ML) - a subtype of AI that employs algorithms through data analysis without being explicitly programmed. ML tends to be associated with solving problems of logic after learning from human-defined teaching cases typical of an ANN (1).

Magnetic Resonance Imaging (MRI) - a complex medical technique that can also be used for *in vivo* medical imaging, to form images of the body's anatomy and physiological processes. In essence, it can be considered to be based on a "magnet-like" behavior of stable atomic nuclei with an odd number of protons in a magnetic field. The simplest such nucleus is the hydrogen nucleus in the constitution of water – which is, in fact, a proton, and will behave like a small magnet, participating in "resonance" and then returning to the initial state, through "relaxation". As a result, MRI images will be able to provide information about the proton density in the body, which will be higher where the amount of water is higher. So, information will be related to the liquid structure of the examined formations. Complex definition can be found in (15).

Mobile Health (mHealth) - is the practice of medicine and health care over mobile computer devices. As an industry, the mHealth field has seen exponential growth in recent years thanks to widespread use all over the world and increasingly accessible mobile technology (16).

N: Natural Language Processing (NLP) - a subfield of AI. It helps computers process and understand the human language so that they can automatically perform repetitive tasks. Examples include soft translation, summarization, ticket classification or spell check (8).

Next Generation Data - rely on software-defined technologies as their logical layer, allowing for better control of physical and virtual resources. One of the biggest priorities of a next generation data center is automation-streamlining workflows and reducing the manual upkeep (17).

P: Personalized medicine (PM) - seek to improve stratification and timing of health care by utilizing biological information and biomarkers on the level of molecular disease pathways, genetics, proteomics as well as metabolomics (18).

PET - acronym widely used to mean

Positron Emission Tomography, an *in vivo* technique in the imaging field of nuclear medicine that provides functional images by using radiotracers with positron-emitting radioisotopes and tomographic acquisition, with the reconstruction of images in sections. Because PET radiotracers cellular localization is related to the metabolic activity of the cells, PET brought functional images at the new level of molecular imaging (19).

PET-CT - *in vivo*, fused, functional (PET) and structural (CT) imaging.

PET-MRI - *in vivo*, fused, functional (PET) and structural (MRI) imaging.

Podcast - is a broadcast that is placed on the Internet for anyone who wants to listen to it or watch it. Some radio stations already are posting their talk shows on websites to reach podcast audiences. Podcasts and their use in medical education is growing and becoming more popular, all while not knowing what podcasts are available for each specialty (8).

Precision medicine - aims to improve patient outcomes by stratifying or individualizing diagnosis and treatment decisions. The term relies on genetic, phenotypic, or psychosocial characteristics to provide precise identification of patient subsets for treatment targeting (20).

R: Radiopharmaceutical - also named **Radiotracer**, the substance that is administered to the patient in nuclear medicine techniques. There are two categories of radiopharmaceuticals: radioisotope alone (examples 131I, 201Tl) or radioisotope + vector molecule (in this chemical compound one or more atoms are replaced by a suitable radioisotope). The radioisotope is a gamma (in the case of SPECT) or positron (in the case of PET) emitter. The radiopharmaceutical is administered intravenously orally or by inhalation, depending on the type of investigation, circulates into the blood and is captured cellularly through an uptake mechanism in relation to the phenotypic characteristics of the visualized cells/tissues. A gamma radiation will be emitted from the uptake structures and will be detected by a gamma camera type device (19).

Radiography - an *in vivo* imaging technique from the field of **Radiology** (medical imaging domain that uses *in vivo* medical X-ray imaging to diagnose diseases and guide their treatment). It uses X-rays that will be attenuated differently in relation to the tissue density, making evidence of the structural characteristics of the internal tissues/organs. The images are recorded nowadays be the mean of a computer and can be delivered on an information support (electronic, currently) (9).

S: Smart health (sHealth) - a healthcare system that enables patients and doctors to communicate with each other and remotely exchange information monitored, collected, and analyzed from patients' daily activities via the IoT (21, 22).

Smart healthcare - can be defined as an integration of patients and doctors onto a common electronic platform for intelligent health monitoring by analyzing day-to-day human activities.

Smart data - data from which signals and patterns can be extracted by intelligent computer algorithms (8).

Smart patient care - system that includes electronic devices, being needed to help nurses make more informed prioritization decisions between responding to alarms and ongoing tasks and, finally, assist them in adjusting their work priorities in various situations (23).

SPECT - acronym for **Single Photon**

Emission Computed Tomography. A nuclear medicine procedure in which images are acquired through the rotation of a gamma camera around the patient and takes images from different angles, which a computer then uses to form a tomographic (cross-sectional) image, within different sections (classical sagittal, transversal, coronal but sometimes also, dedicated). The images are the result of the emission of gamma radiation, after the administration of a radiotracer that includes a gamma emitter radioisotope (2).

SPECT-CT - acronym for **Single Photon Emission Computed Tomography–Computed Tomography**. Fused image technique that superposes functional (SPECT) image with anatomical (CT) image (24).

Support vector machines (SVMs) - a set of supervised computers learning methods used for classification, regression and outliers' detection (25).

Synthetic intelligence (SI) - provides authentic higher-order reasoning using technology like quantum logic, while AI simply imitates human thought (1).

T: Telehealth - the delivery of health care services, where distance is a critical factor, by all health care professionals using information and communication technologies for the exchange of valid information for diagnosis, treatment and prevention of disease and injuries, research and evaluation, and for the continuing education of health care providers, all in the interests of advancing the health of individuals and their communities - the World Health Organization definition. Support and promote long-distance clinical health care, patient and professional health-related education, and public health and administration (26, 27).

Telemedicine - Telemedicine is the use of telecommunications technology to deliver health care to populations with limited access to care (28). Also, can be defined as the two-way, real time interactive communication between the patient and the physician or practitioner at distant site. Starting from this basic definition, new terms continue to appear, in relation to the scope of telemedicine, for example: telepathology (remote viewing of microscopic images), telerehabilitation, tele-oncology, tele-education and the list rest open.

Theragnostic - a term that refer to a treatment strategy that combines therapeutics with diagnostics. It associates both a diagnostic test that identifies patients most likely to be helped or harmed by a certain medication, and a targeted drug therapy based on the diagnostic test results. Usually is developing in oncology (29). Both parts rely on the same tissular principle through the same specific phenotype markers, but the physical used agent must be no harmful for diagnostic and destroy the identified tumoral tissue, in the therapy part.

U: US - Abbreviation that stands for **ultrasound imaging** (or **echography**, **sonography**). This *in vivo* imaging technique uses high-frequency sound waves to view inside the body. Because ultrasound images are captured in real-time, they can also show movement of the body's internal organs as well as blood flowing through the blood vessels, without any invasiveness (9).

V: Vector molecule - a molecule (chemical compound) that can be labeled with a radioisotope suitable for the diagnostic detection/treatment in nuclear medicine and is used to direct this radioisotope to a tissue/organ that will capture it preferentially, sometimes specifically, in relation

to its phenotypic characteristics. In this way, by detecting the emitted gamma radiation, it is possible to visualize the tissue in relation to its functional characteristics, acquiring a map of distribution of the radiotracer in the explored organ (30).

No doubt, the list can go on. We hope that through this introductory material we have helped to clarify some notions for all those involved in IT software development collaborations for medical use, and, above all, that we have opened the readers' appetite to develop and clarify as many terms as possible from the avalanche of neologisms appearing at the IT / Medicine interface, for the benefit of the development of the medical fields and, not lately, of the patient.

NEWS

DIAGNOSTIC ACCURACY OF POINT-OF-CARE LUNG ULTRASOUND IN COVID-19

The aim of this single-center, prospective, diagnostic accuracy study was to determine the diagnostic accuracy of Point-of-care Ultrasound **(**POCUS) for the diagnosis of pulmonary manifestations of COVID-19 in patients presenting to the ED. A convenience sample of 100 patients with suspected COVID-19 was enrolled between 14 April and 22 April 2020. POCUS had a sensitivity of 89%, specificity of 59% and a NPV of 93% compared with PCR (or CT scanning if negative PCR) in diagnosing pulmonary manifestations of COVID-19. Pulmonary manifestations of COVID-19 may be excluded by POCUS in patients without previous cardiac or pulmonary medical history. In conclusion, POCUS of the lungs could serve as a valuable, easily accessible and radiation-free tool for excluding pulmonary manifestations of COVID-19 in patients in the ED at the point of assessment, especially in patients without previous cardiopulmonary disease (Haak SL, Renken IJ, Jager LC, Lameijer H, van der Kolk BBY. Diagnostic accuracy of point-of-care lung ultrasound in COVID-19. *Emerg Med J* 2021; 38(2): 94-99 / doi: 10.1136/emermed-2020-210125)

EDITORIAL

ARTERIAL STUMP MEASUREMENT: QUALITY INDICATOR IN COLORECTAL SURGERY

Measuring quality of surgery in colorectal resections for cancer has become an important subject of research since the principles of total mesorectal excision (TME) for rectal cancer and complete mesocolic excision (CME) for colon cancer have been brought forward. CME surgery proved to decrease local recurrence in colon cancer to 3.3% (1, 2). Similarly, TME was shown to drastically improve surgical outcomes in rectal cancer.

CME as described firstly by Hohenberger *et al*.(1) is based on three principles: (1), mobilizing the colon in the natural, embryological planes, maintaining an intact, spillage-free mesocolon; (2), ligation of the main vascular pedicle at its origin (i.e., central vascular ligation - CVL), ensuring removing the entire mesenteric root along with the central lymph nodes and (3), adequate distal and proximal margins of at least 5 cm.

While the intact dissection of the mesocolon and ensuring negative longitudinal margins has become well standardized and adopted by most surgeons, controversies still exist on the ideal location of CVL and whether CVL does actually impact survival. Adequate trials to define the ideal CVL point at which recurrence rate is improved compared to conventional surgery are lacking mainly because measurable indicators are not well standardized. One may predict the point of CVL indirectly by measuring the distance from the margin of the tumor to the apex of the specimen, but we must be aware of the natural anatomical variability in mesocolic area and pedicle length among patients, which will bias results.

One simple, non-invasive way of measuring the point of CVL and thus predicting the extent of apical lymph node dissection is to measure the length of the arterial stump on postoperative contrast enhanced computed-tomography (CT) scans. This is the most direct way of comparing oncological outcomes between CVL and non-CVL colectomies and can be done even in a retrospective manner. Both the ileocolic artery (ICA) and inferior mesenteric artery (IMA) stumps are readily visible on standard CT scans which are part of the routine colorectal cancer follow-up. Although it seems an innovative, simple technique, and we have tested its feasibility in our own previous studies (3, 4), it has yet to reach significance in clinical practice. Currently on PubMed there are seven original articles (3, 5-10) which tested the value of arterial stump measurement as a surgical quality marker.

Stump measurement: is it difficult?

The most valued trait of arterial stump measurement it`s the simplicity of assessing the length on routine postoperative CT's, which are already done as a standard cancer follow-up, thus measurements can be done retrospectively, and lengths can be easily linked to survival of patients. While some studies performed mesenteric enhanced CT's, in our experience this is not

required. Apart from the visible contrast, arterial stumps can be identified due to tip granuloma which appears at the ligation point, or, if clips are used, then measurement becomes even easier, by visualizing the radiopaque clip at the tip of the contrast enhanced stump. Most studies used experienced radiologists to perform stump measurements, mainly to improve reliability of results, but this can be done by surgeons as well if they are used to analyzing CT images of colonic anatomy in their practice. In general, surgeons are able to identify the correct stump length in at least 80% of cases when the radiologists' measurement is considered the benchmark length. On the right side, the superior mesenteric vein (SMV) and superior mesenteric artery (SMA) are identified. The ICA stump is identified as the last vessel arising from the SMA on the right side. On the left side, the inferior mesenteric artery (IMA) can be identified at the level of the 3rd lumbar vertebrae with a left trajectory. The stumps are measured from their origin to the clip or, if a clip was not used, a suture granuloma is usually visible. Overall, none of the included studies had issues or discussed technical difficulties in measuring the arterial stump both at the right and left colon.

Arterial stump:
marker of surgical quality?

Correct reporting on surgical specimens has become a requisite in any cancer centre. The advent of CME and TME and their impact on recurrence rates in colorectal cancer has made institutions to audit their specimens and ensure an adequate standard is met. Currently, measurements on fresh specimens are the norm and proved to predict outcomes. In our practice, among other institutions, stump measurement has become, so far, a complementary indicator of extent of resection. It is logical to assume that stump length is inversely proportional to all other macroscopic pathological measurements on the specimen, as the stump is anatomically part of the specimen, representing the tip of the pyramid both on the right and left colon, thus a shorter stump will naturally lead to a longer and wider specimen, a longer distance from the tumor to the apical vascular tie and a higher lymph node yield. All these pathology measurements proved to have prognostic implications and are regarded as standard indicators for quality of surgical specimens. For clinicians to embrace and use stump measurement as a quality marker, one must prove it has the same sensitivity and specificity while being easier to measure by non-pathologists.

Arterial stump: prognostic marker?

Hypothesizing that the stump length could correlate with the rate of local and/or systemic recurrence is an intriguing scenario. Increasing number of studies praise the importance of apical lymph node dissection especially in cN+ tumors, where the rate of central lymph node metastasis is higher11-15. In patients with positive central lymph nodes leaving a short arterial stump (less than 1.5cm) is recommended in avoiding local and systemic recurrence (17, 18, 19). More so, only by leaving a short stump, surgeons can manage to dissect the mesocolon fully intact up to its root. Some argue that leaving a longer stump while still performing central lymphadenectomy is and adequate replacement (20, 21, 22). This holds true for early stage cN0 cancers, where positive lymph nodes at the edge of the mesentery are very unlikely; however, in more advanced tumors complete meso-

colic excision up to the root of the peritoneum is the standard procedure with the best recurrence free survival rates and this can be achievable only by ligating the main pedicle at its origin leaving a small stump. Thus, arterial stump length may be regarded as an indirect marker of CME and CVL. Despite this, no study in current literature analyzed the prognostic implications stump length and this should be addressed. If the stump length proves to predict survival, then it would be a simple adjunct tool to assess whether a patient would benefit from adjuvant treatment.

In conclusion, postoperative arterial stump measurement after colorectal resections seems to be a simple tool to assess surgical quality, however the evidence is poor. Institutions that practice stump measurement should retrospectively compare the stump length with other pathology measurements and, more importantly, to assess whether leaving a shorter stump has an impact on recurrence free survival and, if it does, then a minimal accepted length should be brought forward.

PALLIATIVE MEDICINE - BEYOND ADVANCED CANCER CARE

Nowadays, medicine has the same value and meaning, and is answerable to the same formidable requirements it has always been. Medicine must soothe, heal, prevent and limit the spread of disease. A physician has the opportunity to live inspiring moments while brings the very sick patients again to life and these rare moments will uplift him in the most difficult situations. In some specialties, such moments could repeat more often as in surgery, emergency medicine and sometimes in cardiology or neurology. In the majority of time, the practicing physician has to deal with chronic diseases, some of them which aggravate and complicate itself, ultimately conducting to organ failures and a very poor quality of life. Moreover, due to the success of medicine in preventing some diseases, in treatment of infectious diseases and in effective treatment of ischemic heart disease, diabetes mellitus etc. people live much longer, and experience new problems related to advanced age (1). Death, the termination of life is seen as a disease and drained by any spiritual meaning. Twenty-one century medicine is dealing with termination of life problems, with the emerging "assisted suicide" solution for the difficulties related to advanced diseases and advanced age and with a huge pressure on health system done by chronic advanced diseases with low quality of life and disability (2). New rules, new laws, new concepts are required to respond to new approaches and needs. A different health system organization is needed.

An example of a disease which needs a new approach is decompensated liver cirrhosis.

Cirrhosis represents the final irreversible stage of chronic progressive liver disease. The patients' prognosis depends on etiology, comorbidities, and especially stage and complications (3). Cirrhosis stages are classically seen as: compensated and decompensated, the last one being defined by the occurrence of complications as: ascites, spontaneous bacterial peritonitis, hepatorenal syndrome, jaundice, upper gastrointestinal bleeding by variceal effraction, hepatic encephalopathy (4). Other complication which may darken the prognosis of cirrhotic patients is hepatocellular carcinoma, often diagnosed in advanced stage. „End-stage liver disease" is another term used to describe advanced liver diseases stage, characterized by chronic liver failure, and decompensated cirrhosis, just to emphasize the irrevocable severe course of the illness and the inevitable somber lethal outcome.

However, liver transplantation emerged as an outstanding cure for patients with advanced cirrhosis, ensuring lifesaving, life prolongation and also regain of life quality. There are well-defined classification systems, which aim to objectively establish the indication for liver transplantation for each individual patient with cirrhosis. The MELD („*Model for End-Stage Liver Disease*") score, able to predict prognosis of cirrhotic patients, has been officially adopted by United Network for Organ Sharing and Eurotransplant as a tool for

prioritizing patients awaiting liver transplantation (5). Using MELD score (which takes into account serum bilirubin, serum creatinine, and the international normalized ratio for prothrombin time), patients are assigned a score from 6 to 40, which correspond to estimated 3-months survival rate of 90% to 7%, respectively (6). Patients with MELD scores 15 or greater are considered candidates for liver transplantation, while patients with lower values are considered as having a better prognosis without. Still, patients with cirrhosis may present important serious complications, which are not always reflected by a high MELD score, but which equally negatively affect their survival rate. For instance, spontaneous bacterial peritonitis or variceal hemorrhage due to portal hypertension, are poor prognostic indicators.

Undoubtedly, liver transplantation is a potential definitive curative treatment for advanced liver disease. However, decompensated cirrhosis remains a disease with variable prognosis and unpredictable outcome. Even with the hope of liver transplantation, patients are at risk for adverse outcome, with, generally, an average survival without liver transplantation of approximately two years (7). Many patients on the waiting list die, with an estimated percentage of 15% annually (8), while, usually, another 10% are delisted in the same year due to worsening of their condition (9). Additionally, liver grafts are limited, and the number of patients needing liver transplantation exceeds the organ availability. Moreover, liver transplantation is not a *panacea*, as many patients are not candidates, due to comorbidities, or being "too sick" to be transplanted, or precluded by social factors.

Thus, palliation should not be limited to end-of-life care but provided throughout the entire trajectory of illness. Palliation should not be understood (only) as care measures offered to patients at the end of life, having as main aim the sufferance relief, but as maximal life-prolonging therapeutic actions, including curative approach of complications.

Contrary to appearances, palliative care and liver transplantation are not mutually exclusive. In fact, keeping the end-stage liver disease patient alive enough and well enough to be transplanted, is the key for cure. Providing supportive care for patients with complications needing transplantation may be the redeeming quality to survive until liver transplantation.

However, hospital readmissions in patients with decompensated cirrhosis, as well as their hospital lengths of stay are challenging matters. Readmission rates of cirrhotic patients vary depending on the follow-up duration and the studied population, different studies showing early readmission rates, defined by another hospitalization due to an acute situation within 30 days of the index hospitalization, from 20% to 50% (10,11). Readmission rates increase with the duration of the follow-up period, and the main reasons for early readmission appear to be specific complications as hepatic encephalopathy, variceal bleeding, or infections, as showed by one of our studies regarding predictive factors for the prognosis of alcoholic liver cirrhosis (11). Prolonged length of stay is also an issue in cirrhotic patients' care, representing a supplementary burden for hospitals, especially for those designated to function as emergency units.

Nonetheless, for patients in terminal end-of-life stage, as advanced end-stage liver disease and hepatocellular carcinoma with Barcelona Clinic Liver Cancer stage D

tumor (12), the care will be primarily focused on comfort and alleviating suffering and pain. Hospices are dedicated institutions aiming to assist terminal life stages, targeting comfort and quality of life.

Thus, throughout the entire trajectory of the illness, a dynamic process of identification of patient-centered goals of care is compulsory and of utmost importance. Along evolution, as long as liver transplantation is still an option, management must be centered on life-prolongation measures, complication treatment and preventions strategies for further decompensation, while comfort ensuring will be prioritized as strategy of end-of-life care. However, there are still gaps in defining end-of-life criteria, as long as prognosis and life expectancy in cirrhosis are not precisely predictable.

As physical deterioration and psychological suffering coexist in advanced liver disease, symptoms control and psychical needs are both equally important targets to consider. Healthcare services should offer not only physical medical care, but also mental and social support, towards patients and also their families.

Appropriate palliative care in advanced liver disease is a decisive determinative factor for patients' outcome, in terms of life and death, literally. This fact, as well the need to offer the optimal tailored assistance, was understood properly in the recent years by all the caregivers, and the interest in palliation in cirrhosis is growing.

Therefore, adapted strategies should be wisely adopted for every patient with liver cirrhosis, in order to obtain both prolongation and quality of life. Understanding each individual cirrhotic patient's needs, rethinking care strategy and, if needed, restructuration of hospitals, defining special care units, might be the key issues to ensure the best end-stage liver disease care.

THE IMPACT OF CHRONIC DISEASE ON STUDENTS' QUALITY OF LIFE

In 2020, there were about 18 million tertiary students in Europe (1). The average of those reporting chronic health conditions was around 18% in Switzerland, with the highest level of 39% in Iceland and the lowest of 7% in Romania, Albania and Serbia (2). The health status of students should be a concern for health professionals, alongside academics, as higher education plays an important role in society, increasing people's well-being, fostering development and economic growth. However, our knowledge of the impact of chronic illness on university life is limited (3), with minimal research on the differences and similarities of the academic experience of students with chronic illness compared to students without health difficulties (4) but also how universities can support these students (5). As a result, through this exploratory narrative review we aim to synthesize some key ideas about the impact of chronic illness on students' quality of life and formulate a series of recommendations that can be followed by university support services to encourage quality of life and academic adjustment for this group of students.

Chronic diseases are medical conditions with implications on the main dimensions of a person's life, felt on a long-term or even lifelong basis, accompanied by a series of emotional, social and lifestyle challenges (6). Young people with a chronic illness often report feeling that their chronic illness prevents them from living a normal life (7).

Chronic diseases are diverse and can cause varying degrees of impairment, but thanks to advances in medicine, increasingly young adults are pursuing higher education and can even achieve very good health outcomes (8). However, unlike students without significant health problems, students with chronic conditions have lower graduation rates and quality of life (9). All students, especially first-year (10) and final-year (11) students, experience challenges in adjusting to the academic environment, such as difficulties with sleep, learning, engagement, homesickness, and difficulties with roommates (12), but for those with chronic illnesses, health care challenges are also added (13). In general, students with chronic illnesses may face more difficulties in pursuing and completing higher education (3), experience stress related to adapting to academic and social demands, and also feelings of loneliness and isolation (9).

Despite the well-known idea that student hood is a very challenging time, and the fact that quality of life assessment has been evolving since the 1970s, too little attention has been paid to the quality of students' lives (14). The World Health Organization (15) defines quality of life as "people's perception of their position in life in the context of the culture and value systems in which they live and in relation

to their goals, expectations, standards and concerns". It is, therefore, a subjective perception of the degree of contentment, satisfaction, towards four domains: physical, psychological, social and environmental, not just the absence of illness or disability (16). According to Li and Zhong (17), factors that can negatively impact on quality of life in university students can be grouped into six categories. The above authors conducted a narrative review and identified the following variables for the six categories of factors: (a) demographic factors: gender, age, religion, ethnicity, urban/rural origin, family income, only-child status, family type and parent-child relationship; (b) physiological factors: musculoskeletal pain and chronic diseases; (c) psychological factors: anxiety/depression, social phobia, attention deficit disorder, and childhood neglect/abuse; (d) social factors: experiences of neglect; (e) lifestyle and behavioral factors: physical activity, sedentariness, and exercise; and (f) academically relevant factors: major, interest in learning, academic stress, and academic performance.

In general, the support provided by universities is appropriate for good or permanent, predictable and stable health conditions, which is at odds with the unpredictability of chronic diseases. Diseases such as asthma, lupus and multiple sclerosis are notorious for periods of crisis, when symptoms are actively manifest, followed by periods of remission, for example. Such changes, amidst the rigidity of educational institutions, lead to reduced employability and reduced chances of completion for students (18). Moreover, there are also situations under which educational institutions may be rigid, undesirable or unable to adapt services to the specifics of chronic illness and the needs arising from it (3). In university settings, according to the study by Hamilton *et al.* (4), students face misconceptions about chronic illness, feelings of inequality and being undervalued. They have the perception that many staff members do not understand them and therefore 'politicize' academic regulations rather than adapt them for their chronic illnesses. Toller and Farrimond (3) identified three main difficulties faced by chronically ill students in their undergraduate studies, namely the reorganization of daily activities according to the difficulties of the sick body, institutional support that is not adapted to the unpredictability of the demands of a sick body, and poor awareness of chronic diseases. Added to all of these there are also financial difficulties, as some chronically ill students are dependent on loans specifically for students (7). Thus, it appears that the challenges faced by students with chronic diseases in the university environment are particular, with the need for knowledge and adaptation on the part of universities being a pressing one, especially amidst the increasing prevalence of chronic diseases among students (19, 20).

The aim of the review is to synthesize a range of relevant information about students' quality of life, with a focus on the quality of life and university experience of those with chronic diseases.

QUALITY OF LIFE OF STUDENTS VERSUS QUALITY OF LIFE OF THE GENERAL POPULATION BEFORE AND AFTER COVID-19 PANDEMIC

Compared to the general population, both before and during the COVID-19 pandemic, students had a lower quality of life (21), being extremely vulnerable to

mental health problems (22). Interestingly, this result is concluded even though they associate university studies with improving their quality of life in the future. One possible explanation may be that during their years of study they are stressed and anxious because of academic obligations, their own and their parents' high expectations of performance and their desire to meet them (23).

According to the survey conducted by UNESCO (24), in April 2020, as a result of the COVID-19 pandemic, 1.5 billion learners, a large proportion of them students (25), had to stay at home and take online courses as educational institutions were closed. This, along with other restrictions, led to reduced or even no social interaction, worries about finances, fear, the need to adapt to online learning and new ways of assessment, frustration and boredom (26, 27). Cheah *et al.* (25) identified that the psychological dimension of students' quality of life suffered most as a result of movement restrictions in the pandemic. Although, the social dimension was also affected as a result of social distancing, communication via technology was a buffering coping (25).

Leong Bin Abdullah *et al.* (28) assessed students' quality of life and associated factors during the COVID-19 pandemic and identified that student scores on the psychological and social dimensions of quality of life were lower than non-pandemic norms of the general population, while scores on the physical health and environmental dimensions of quality of life were comparable. A positive effect on the quality of life of the students investigated by the previously mentioned authors was the higher number of hours of classes attended online, along with higher social support from significant others when demographic, personal, and clinical variables were controlled. For the same students, quality of life was negatively impacted by the high prevalence of COVID-19, high levels of depression, stress, and frustration arising from study discontinuation (28). Other factors that could explain the impairment of students' quality of life during the pandemic were high levels of distress, anxiety, depression and suicidal thoughts (22, 29).

On a more specific level, both relative to the general population and to other categories of students, medical students appear to have a worse quality of life, mainly due to lack of leisure time and fatigue (14, 30). At the same time, there are also research studies in which medical students have better, or comparable, quality of life outcomes to other categories of students (31). These differences could be explained by some specific characteristics of the investigated populations (14). Although no clear trend can be identified in this regard, it is certain that, regardless of their major, students have a lower quality of life than the general population.

QUALITY OF LIFE OF CHRONICALLY ILL STUDENTS COMPARED TO STUDENTS WITHOUT SIGNIFICANT HEALTH DIFFICULTIES

According to the scientific literature (21, 30), students have a lower quality of life than the general population. Those with chronic illnesses even have significantly lower quality of life and higher levels of anxiety and experiential avoidance than students without significant health difficulties (32). One explanation may be the ma-

jor changes that occur in a young person's life when they acquire student status. They either start commuting or move away from home and have to take care of themselves, from housework to paying the bills, they have to adapt to a new city, a new social and educational environment. All these challenges mobilize a person's resources and can be associated with significant distress, which explains the lower quality of life. On top of all this, for people diagnosed with a chronic illness, the demands and restrictions of experienced medical conditions are added, leading to an even more noticeable decrease in quality of life (33).

Chronic diseases are diverse and can have varying degrees of impairment, which will be further associated with different levels of quality of life and, in general, school absenteeism. Wikel and Markelz (8) argue that the more a student misses classes, the more their academic performance will be affected, with this correlation being particularly common among students with chronic illnesses. Chronic illness predominantly causes a negative impact on students' quality of life, with acute feelings of loneliness and poorer academic performance (34), compared to students without chronic medical conditions, who perform better on both variables (9). Thus, chronic illness may also have significant effects at the academic level, in addition to those determined at the physiological level, as sick students have lower retention and graduation rates (9), while students without chronic illness and with a better quality of life are able to access resources and services available at the university, thus having a better integration into the social and academic environment. Gazibara *et al.* (35) also found that students with chronic diseases have a worse quality of life than healthy students, with female students scoring lower on the physical and mental functioning dimensions compared to male students. Similarly, students with irritable bowel syndrome have lower quality of life than students without this chronic health condition (14, 36).

Concluding, regardless of the health status of students, universities could design and implement health promotion and prevention activities. These institutions should ensure that they use useful channels of information so that the whole academic community is made aware of the resources available for students with chronic diseases on campus and in the community. Better screening to identify students with chronic illnesses in their first year of study and including them in a mentoring programme where students with experience of managing chronic illnesses support new ones can improve their sense of belonging and integration into the academic community. Universities may consider including in their academic regulations some flexibility in academic work, such as extending deadlines for projects and exams, to allow students with chronic illnesses to better manage their medical needs and meet their academic obligations at the same time. Last but not least, financial support is important, given that some students are dependent on loans specifically targeted for them in order to support themselves and cover the costs of treatments.

FUNDING

This work was co-funded by the European Social Fund, through Operational Programme Human Capital 2014-2020, project number POCU/993/6/13/153322,

project title "Educational and training support for Ph.D. students and young researchers in preparation for insertion into the labor market".

CONSIDERATIONS REGARDING TUBERCULOSIS AND VIRAL INFECTIONS IN CHILDHOOD (Abstract): Tuberculosis is a major public health problem worldwide, with mortality rates that have not decreased significantly in many regions. **Aim**: to evidence a correlation between antecedents of varicella and other infectious diseases caused by viruses in childhood and the subsequent diagnosis of tuberculosis in children and young adults. **Materials and methods**: a descriptive study was conducted on a group of 507 children and young adults, hospitalized for a period of 5 years, in a pneumology hospital from Eastern Romania. **Results**: The frequency ratio indicated a predominance of females (53.8%), from the urban environment (52%), mean age = 11.40 years, close to the median value. Infectious diseases were identified in 38.7% of patients. The most common infections were varicella (28.8% of total; 44.5% aged 8-14 years, p=0.004) and mumps (15.4% of total; 52.6% aged 15-23 years, p=0.001), but rubella (4.7%) and measles (4.1%) in antecedents were also identified. **Conclusions**: Our study highlighted the hypothesis that, by frequency, infectious diseases in antecedents, especially varicella, could predispose to a later TB infection, in children aged of 8-14 years. **Keywords**: TUBERCULOSIS, CHILDREN, VARICELLA, INFECTIOUS DISEASES.

Tuberculosis (TB) is a major public health problem worldwide, with mortality rates that have not decreased significantly, and in some regions are increasing (1). The recent ECDC rapport showed that more than 230,000 people were diagnosticated with TB in 2021, with an incidence of 25/100,000 inhabitants. For the first time in two decades, the incidence rate is estimated to have increased by 1.2% from 2020, reflecting the impact of the disruption of TB surveillance caused by the COVID-19 pandemic (2).

The TB mortality rate at the regional level decreased cumulatively by 52%, from 4.4 to 2.1 deaths per 100,000/inhabitants, in the last decade, when the average annual decline in TB incidence rate was 4.6%, which is significantly higher than the global rate of decline in TB incidence (2%) and the fastest decline in the world compared with other regions. Romania (with -7.9%) was among countries with the highest annual decline rate (2).

TB leads to a latent, asymptomatic infectious process and children under the age of 5 years are more exposed due to an immature immune system. In children with direct and

chronic contact with a carrier, TB can progress rapidly, with respiratory symptoms, but sometimes with miliary tuberculosis and tuberculous meningitis. Diagnosing, treating and preventing TB in children can be difficult, and failure to diagnose can have devastating consequences both for the child and the family, as well as for the community and health services (3).

In areas with at least 100 new and relapsing TB cases, the proportion of TB in children (0-14 years) varied between 1-3%. The difference in childhood TB case rates between regions may reflect differences in case-finding practices (such as contact tracing), the age structure of the population, and the underdiagnosis of pediatric TB. The average percentage of new and relapsing TB patients under the age of 15 in the EU was 4.1% (2).

The evolution of latent infection to active TB is influenced by a series of risk factors, such as age, respectively children under 5 years old, or teenagers (4). Certain comorbidities, especially those that induce a degree of immunosuppression of cellular immunity (5), diabetes, malnutrition, immunosuppressive treatments, chronic renal failure, HIV/AIDS infection or childhood viral infectious diseases (6) are considered important risk factors, which leads to the progression of a latent tuberculosis infection to the disease.

The study aim was to highlight a correlation between antecedents of varicella and other infectious diseases caused by viruses in childhood and the subsequent diagnosis of TB in children and young adults, in an Eastern region of Romania, during a transition period, when varicella vaccination had just entered (7) the National Immunization Programs in European Union.

MATERIALS AND METHODS

A descriptive study was conducted on a group of 507 patients, hospitalized for a period of 5 years (2005-2009), in a pneumology hospital from Eastern Romania. The *inclusion criteria* in the study were the clinical diagnosis of TB, the pediatric age groups and the young adult up to 24 years, and the *exclusion criteria* were the invalidation of TB and age over 24 years.

Statistical methods

The data were centralized in an SPSS 18.0 database and processed with the statistical functions to which they lend themselves, at the significance threshold of 95%. The linear trend is a method of predicting the evolution of the disease in the following period.

In the calculation of the significant difference between two or more groups, depending on the distribution of the value series, at the significance threshold of 95%, for the quantitative variables, we applied: a) *t-Student test* - parametric test that compares the mean values recorded in two groups with normal distributions; The test calculates a *t* based on the mean and standard deviation for each batch, depending on the number of degrees of freedom (df). Starting from the "null hypothesis", which assumes that there is no difference between the studied groups, calculating the value of t and comparing it with the tabular *t*, if the calculated value is greater than the tabular one, then the null hypothesis is rejected, and the difference is declared "statistically significant". The unanimously accepted significance threshold is 95%, (p=0.05). The smaller the value of p is than this value, the stronger the signifi-

cance; b) *F-test (ANOVA)* used when comparing three or more groups with normal distributions, combined with the application of the Bonferroni correction (Bonferroni post-hoc) to reduce the error rate when testing several hypotheses.

The χ^2 test is a non-parametric test that compares two or more frequency distributions from the same population, it is applied when the expected events are excluded. Sometimes when a frequency in the calculation formula is small, Yates is applied to correct the formula, to get a higher estimate of the difference. If the obtained *p* is lower than the tabular one at the 95% significance threshold, the events are not excluded - in this case, the question arises as to whether they are dependent.

RESULTS

The highest number of children diagnosed with TB was highlighted in 2008 (n=172), representing 33.9% of the total study group, predicting an increasing trend in the following period (y = 87 + 4 .8 x) (fig. 1).

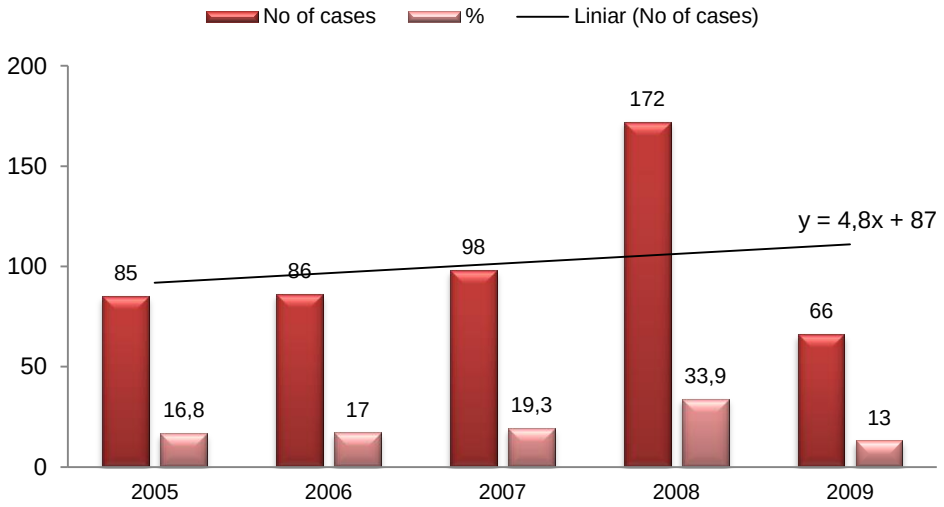

Fig. 1. Number of TB cases in study group

The frequency ratio indicates a predominance of females 1.2 times higher compared to males (53.8% *vs* 46.2%). The frequency of cases from urban environment was slightly higher compared to those from rural areas (52% *vs* 48%) (tab. I).

The age of the children varied from 1 month to 23 years, registering an average age of 11.40 years ± 5, close to the median value of the study group (tab. I, fig. 2).

Antecedents of infectious pathology was identified in 196 children (38.7% of the total study group) (tab. I), from which 41.3% were diagnosed with TB in 2008 (p=0.015) (fig. 3).

Among the 196 cases with TB and *infectious pathology in antecedents*, 104 patients (53.1%; p=0.778) were females, 82 children aged between 8-14 years (41.8%; p=0.001), and 118 cases (60.2% p=0.003) from urban areas (fig. 4).

Other		2	0.4

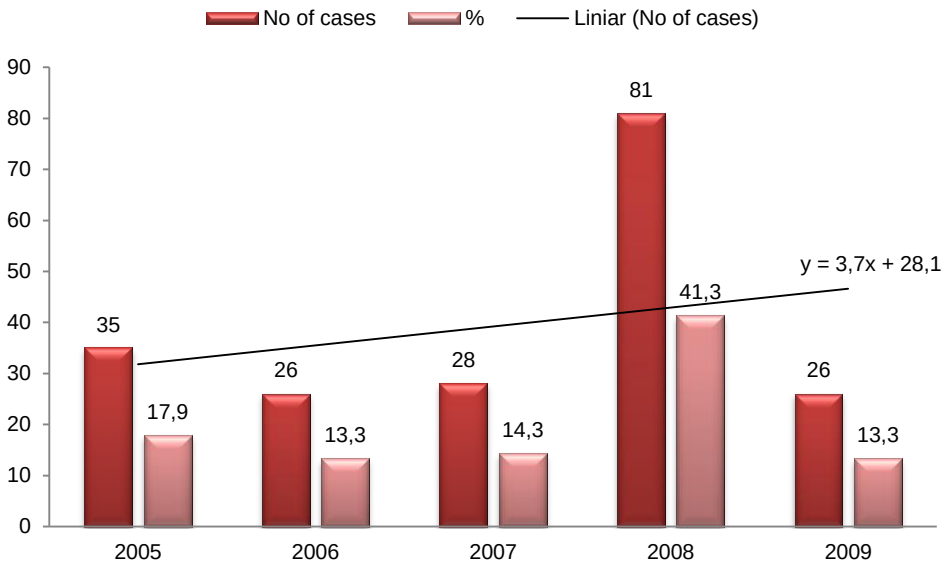

Fig. 3. Distribution of TB cases with infectious pathology in antecedents

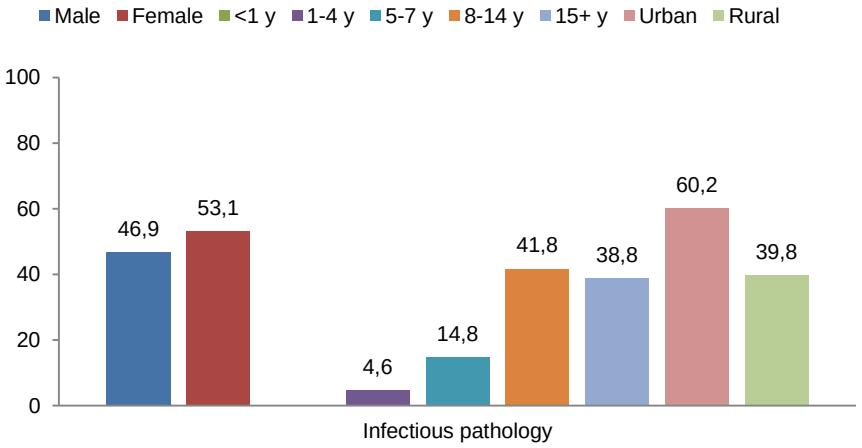

Fig. 4. Distribution of cases with TB and infectious pathology according to demographic characteristics

The most frequent infections were varicella (28.8%) and mumps (15.4%), but a percentage of 4.7% cases of rubella and 4.1% cases of measles in antecedents were also registered (tab. I).

Among the 146 cases with TB and *varicella in antecedents*, 82 children (56.2%; p=0.505) were females, 65 children aged between 8-14 years (44.5%; p=0.004), 89 cases (61%; p= 0.01) from the urban environment (fig. 5).

Among the 78 cases with TB and *mumps*

in antecedents, 40 children (51.3%; p=0.324) were males, 41 patients over 15 years old (52.6%; p=0.001), and 50 children (64.1%; p=0.019) from the urban areas (fig. 6).

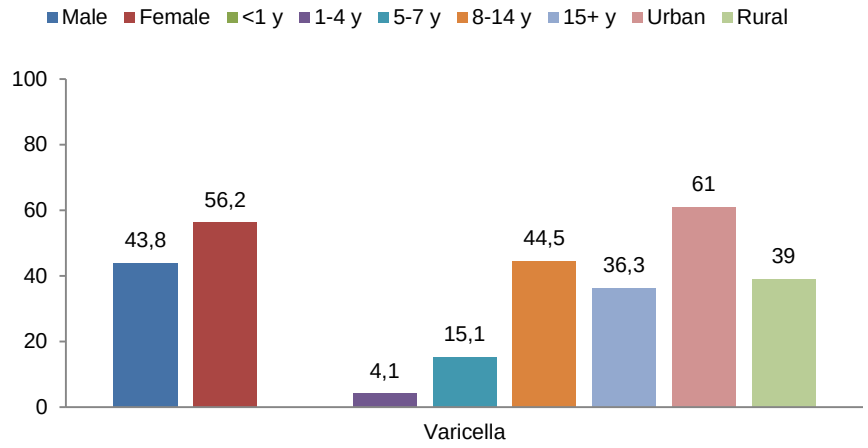

Fig. 5. Distribution of TB and varicella cases by demographic characteristics

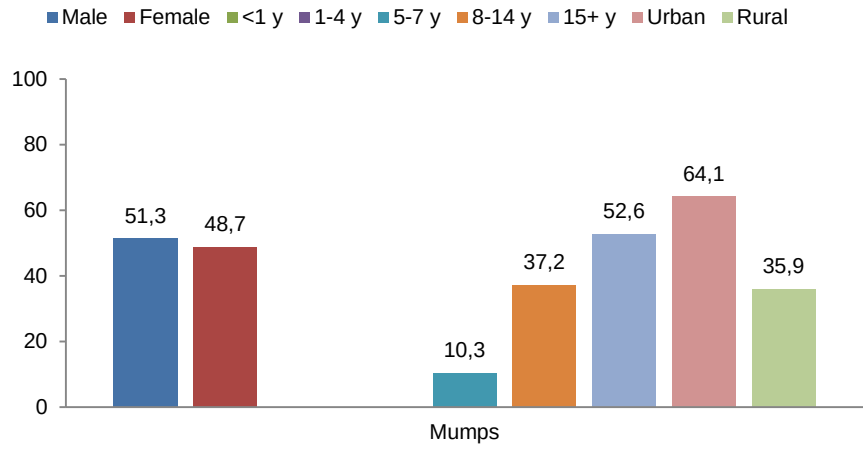

Fig. 6. Distribution of TB and mumps cases by demographic characteristics

Among the 24 cases with TB and *rubella in antecedents*, 16 children (66.7%; p=0.191) were females, 10 children aged between 8-14 years (41.7%; p=0.698), and 19 patients (79.1%; p= 0.005) from urban environment (fig. 7).

Among the 21 cases with TB and *measles in antecedents*, 12 children (57.1%; p=0.303) were males, 11 patients over 15 years old (52.4%; p=0.152), and 13 children (61.9%; p=0.350) from the urban areas (fig. 8).

The Skewness test suggested that the *monitored laboratory parameters* did not have homogeneous values; therefore, the significance tests for continuous variables could not be applied on the study group (tab. IV).

HB-hemoglobin; HT - hematocrit; ESR - erythrocyte sedimentation rate;
Lc- leucocyte count; ALT - alanine aminotransaminase; AST - aspartate aminotransferase.

DISCUSSION

Our study showed that in the group of pediatric patients, 38.7% of children had a history of infectious diseases, of which 28.8% mentioned varicella, 15.4% - mumps, but there were patients who also suffered from rubella - 4.7%, measles - 4.1%. HIV/AIDS was reported in 7 cases (1.4%).

The immune system in children might remain modified after an infectious disease, so that an exposure to *M. tuberculosis* could lead later to TB, especially on this modified immune background. Although several reports have been published, the correlation between infections with other pathogens and TB has not yet been well deciphered (6). A significant epidemiological overlap has been found between certain infectious diseases and TB in children, such as the geographical distribution of an increased prevalence of TB in children and adolescents and a high prevalence of infections with herpes viruses, Ebstein-Barr virus, malaria or HIV/AIDS (8).

A case report of primary cutaneous TB with *M. tuberculosis* was published by researchers in Turkey. The pediatric patient was diagnosed with varicella infection in antecedents. The authors considered that this case could be explained by cellular immunosuppression mediated by the varicella-zoster virus and its involvement in a subsequent TB immune response (9).

Varicella can lead to decreased cellular immunity by decreasing CD4+ T lymphocytes, increasing suppressor CD8+ T-lymphocytes, previous studies showing significant changes in T lymphocyte subsets during the acute phase of infection, including a decrease in CD4+ T cells and an increase in CD8+ T cells (10). Depletion of CD4+ T cells results in higher viral loads, prolonged viremia, and more severe clinical forms (11). CD4+ T cells depletion is accompanied by delayed and reduced varicella-specific antibody and CD8+ T cells responses (12).

Other studies carried out in various regions, have mentioned a correlation between antecedents of infectious diseases such as measles (13) or cytomegalovirus infection (14) and subsequent TB in children or young adults.

The *limitations of our study* referred to a short period of time, the inclusion in the study of certain cases from a specific region of the country, and also to the lack of a control group, in order to be compared

with the cases, for the development of statistically more rigorous conclusions. Moreover, the period of time between the antecedents of infectious diseases and the diagnosis of TB was not mentioned in the medical records from where the data were collected, and this period is useful and important in understanding this correlation attributed to the immune system disturbed (6) by viral diseases.

The *perspective of our study* is related to further research regarding the relationship between TB in children and adolescents and viral infections in childhood, by collecting more details about their epidemiology and demographic data of the study groups. Such information would bring additional data in the diagnosis and treatment of children with TB and would prove useful in vaccination (15) strategies.

CONCLUSIONS

Our descriptive study highlighted the hypothesis that, by frequency, infectious diseases in antecedents, especially varicella, could influence a later TB diagnosis, in children aged of 8-14 years from urban areas.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest and they received no funding.

CLINICAL, PATHOLOGICAL AND MOLECULAR INSIGHTS IN METASTATIC COLORECTAL CANCER WITH BONE METASTASES: A RETROSPECTIVE STUDY (Abstract): Metastatic colorectal cancer (mCRC) represents a complex disease entity characterized by diverse evolutionary trajectories stemming from its inherent heterogeneity, influenced by a myriad of clinical, pathological, and molecular factors. Among the spectrum of mCRC cases, those harboring bone metastases constitute a rare subset. **Materials and methods:** This retrospective study investigated 334 patients diagnosed with mCRC and treated at the Regional Institute of Oncology Iași between 2012 and 2019, of whom 35 manifested bone metastases. Comprehensive characterization encompassing clinical, pathological, molecular features, and prognostic determinants was undertaken for this specific cohort. **Results:** The incidence of bone metastases was recorded at 10.5%, with a median age at diagnosis of 65 years, predominantly affecting males (60%), and demonstrating a predilection for primary tumors located in the left colon (57.1%). Peritoneal (26.5%) and hepatic (17.1%) metastases emerged as frequently associated secondary sites. Histologically, 73.5% of subjects presented with grade 2 differentiated tumors, with KRAS mutations identified in 37.1% of cases, while NRAS and BRAF mutations were detected in 2.8% only. The treatment most commonly used by clinicians was a chemotherapy doublet consisting of a fluoropyrimidine (5-fluorouracil or capecitabine) combined with oxaliplatin in 85.6% of cases, with the addition of an angiogenesis inhibitor (Bevacizumab) in 77.1% of cases. Prognostic indicators revealed a median progression-free survival of 10.7 months and an overall survival of 17.3 months. First line anti-EGFR biological treatment was associated with increased survival, meanwhile peritoneal metastases and NRAS mutation were unfavorable prognostic factors. Despite enriching the understanding of this rare cohort of mCRC patients, the study underscores the imperative for prospective investigations with augmented sample sizes to delineate better the characteristics of this specific subset. **Conclusions:** Patients exhibited worse PFS and OS compared to those described in the literature for other metastatic sites. Among the identified prognostic factors, anti-EGFR treatment was associated with a favorable outcome, while the presence of peritoneal metastases and NRAS mutation were indicative of a poorer prognosis. **Keywords:** METASTATIC COLORECTAL CANCER,

BONE METASTASES, CLINICAL, PATHOLOGICAL AND MOLECULAR FEATURES, PROGNOSTIC FACTORS.

Colorectal cancer (CRC) ranks as the third most prevalent neoplasm worldwide. In its metastatic phase, the median survival typically ranges from 24 to 30 months (1). However, clinical observations have revealed diverse patterns of disease progression that often diverge from established prognostic factors (2).

Metastatic colorectal cancer (mCRC) frequently disseminates to the liver (70%) and lungs (37%), while bone metastases occur less frequently, affecting roughly 3-7% of CRC patients (3, 4). Over the past decade, the incidence of secondary bone lesions has risen due to enhanced survival rates among mCRC patients and advancements in medical imaging technology (5). These patients constitute a distinct subgroup with an unfavorable prognosis, as evidenced by a median overall survival (OS) of approximately 10 months. Prognostic factors for patients with bone metastases remain uncertain, and the development of a well-defined prognostic model is yet to be realized. Furthermore, the role of palliative chemotherapy in CRC patients with bone metastases has received limited investigation (6-8).

This study aims to describe the clinical, histopathological, molecular characteristics, and prognosis of patients with mCRC identified in a tertiary center in Romania to better understand the peculiarities of this type of mCRC and to complement the scarce literature data. Additionally, we attempted to identify prognostic factors for this patient category.

MATERIALS AND METHODS

Aim of the study. This retrospective study aimed to investigate the clinical, pathological, and molecular characteristics of patients diagnosed with mCRC presenting with bone metastases and additionally to assess the prognostic significance of various parameters routinely used in the clinical practice.

Study population and data collection. The study cohort consisted of patients treated at the Regional Institute of Oncology Iasi between 2012 and 2019. Inclusion criteria encompassed patients aged 18 or older, histopathological diagnosis of colorectal carcinoma, imaging confirmation of bone metastases through CT and/or PET-CT and/or MRI and/or bone scintigraphy, Eastern Cooperative Oncology Group (ECOG) performance status of 0-2, and a minimum of 6 months of systemic treatment. Patients who received adjuvant systemic treatment for colorectal cancer CRC in stages I-III were excluded.

Ethical approval was obtained from the Ethics Committee of the Regional Institute of Oncology Iasi and the Ethics Committee of "Grigore T. Popa" University of Medicine and Pharmacy of Iasi.

Data were extracted from the Hippocrate electronic database of the Regional Institute of Oncology Iasi. Various parameters were evaluated in the database, including socio-demographic factors (age, sex), clinical characteristics (ECOG performance status, primary tumor localization, metastasis type), surgical interventions (primary tumor surgery and metastasis excision), pathological features (grading), molecular markers (KRAS, NRAS, BRAF), and survival parameters (PFS and OS).

Statistical analysis. Was performed using *SPSS software version 25.0*. Univariate analysis with the log-rank test and Cox regression were utilized to identify prognostic factors and construct a multivariate model. The study aimed to delineate the clinical, pathological, and molecular profiles of patients with bone metastases and mCRC, while also assessing the prognostic significance of these parameters.

RESULTS

The characteristics of the study population can be seen in detail in tab. I. The median age at diagnosis was 65 years, with 60% (n=21) of patients being male. 88.5% (n=30) had an ECOG performance status of 1. The primary tumor was more frequently located in the left colon, accounting for 57.1% (n=20) of cases. Peritoneal metastases were occurring in 26.5% (n=9) of cases, while 73.5% (n=25) of subjects had G2 tumors. Primary tumor resection was performed in 51.4% (n=18) of patients. Looking at the molecular landscape, KRAS mutation was detected in 37.1% (n=13) of patients, while NRAS and BRAF mutations were each found in 2.8% (n=1) of patients.

BRAF, serine/threonine-protein kinase B-raf.

The median progression-free survival (PFS) in patients with mCRC and bone metastases in the studied cohort was 10.8 months (7.6-13.9), while the median OS was 17.3 months (15.3-19.3) (figs. 1, 2).

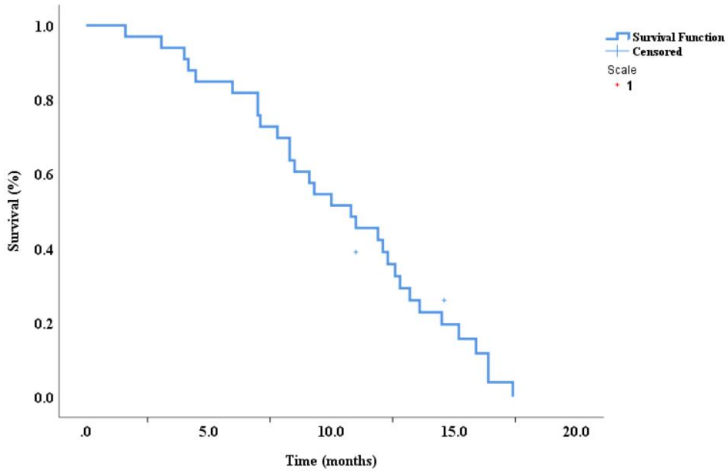

Fig. 1. Progression free survival in patients with CRC and bone metastases

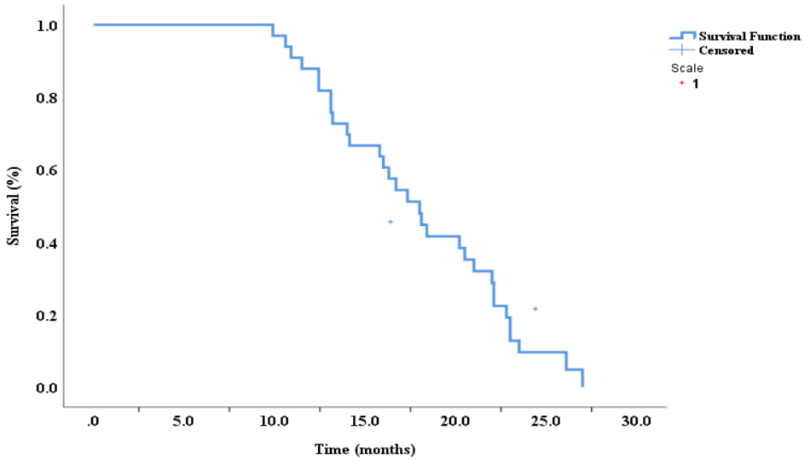

Fig. 2. Overall survival in patients with CRC and bone metastases

We performed univariate analysis to identify prognostic factors for PFS in patients with mCRC and bone metastases. No factors showed prognostic significance (tab. II). Regarding OS, factors identified as prognostic in univariate analysis included sex, peritoneal metastases, NRAS mutations and biological treatment. These factors were subsequently confirmed in multivariate analysis (tab. III, tab. IV).

TABLE IV.

Multivariate analysis for OS

Parameter	p value	Hazard ratio (95% C.I.)
Sex	0.23	1.73 (0.7-4.27)
Peritoneal metastases	0.005	3.66 (1.47-9.08)
NRAS mutation	0.05	11.61 (0.99-31.9)
Biological treatment	0.04	0.26 (0.07-0.98)

NRAS, neuroblastoma ras viral oncogene homolog;

Peritoneal metastases were identified as a negative prognostic factor, with a median OS of 16.4 months compared to 18.1 months in subjects without this type of secondary lesions (P=0.005, HR=3.66, 95% CI, 1.47-9.08) (fig. 3). NRAS mutation was associated with a median OS of 11.5 months, which was 5.8 months less than in patients without NRAS mutation (P=0.006, HR=29.2, 95% CI, 2.68-31.9) (fig. 4.). Anti-EGFR treatment increased OS, with patients receiving Bevacizumab having an OS of 29.2 months compared to 47.8 months in those treated with Cetuximab or Panitumumab (P=0.04, HR=0.26, 95% CI 0.07-0.98) (fig. 5).

DISCUSSION

Regarding the conducted study, we have discussed the most significant clinical, pathological and molecular aspects for patients with CRC and secondary bone lesions.

Incidence. In the current study, we assessed the incidence of secondary bone lesions in 334 patients with mCRC treated at IRO Iași between 2012 and 2019. The overall incidence was 10.5% when considering all types of secondary lesions and 5.1% in patients with only bone lesions.

Bone metastases are exceedingly rare, particularly when occurring as the sole site of metastasis. Existing literature reports a frequency ranging from 5% to 11% (9,10). CRC demonstrates a distinctive metastatic pattern, with the liver and lungs being the predominant sites, while metastases to the adrenal glands, bones, brain, and skin are infrequently documented (3). In a study encompassing 5352 patients over a 25-year span, Kanthan *et al.* identified a frequency of 6.6%, with only 17% of these cases presenting isolated bone metastases, resulting in a frequency of 1.1%. Additionally, 83% of patients with bone metastases were concomitantly associated with other metastatic sites (11). The rarity of such occurrences suggests a distinct biological behavior in metastatic dissemination.

Numerous studies have suggested that the presence of portal circulation significantly predisposes the development of hepatic and pulmonary secondary lesions in mCRC. This predilection may be attributed, as posited by earlier research, to the dense capillary networks present in the lungs and liver, facilitating the lodging and subsequent metastatic growth of CRC tumor cells (7). Furthermore, alongside the hemodynamic theory of metastasis, the theory of organ selectivity also assumes importance. It has been elucidated that each organ harbors a unique tumor microenvironment, inclusive of blood vessels that modulate tumor cell behavior through specific signaling pathways, thereby influencing adhesion molecules crucial for tumor dissemination and implantation (12,13).

Sex. The male gender may potentially correlate with a heightened susceptibility to bone metastases although findings in the literature are inconclusive. A study conducted in China by Liu reported a greater incidence of bone metastases among men. One plausible rationale for this observation could be that men more frequently present primary tumors in the rectum, a site commonly associated with bone metastases (5). Similarly, a study by Riihimaki *et al.* demonstrated a significantly elevated risk of bone metastases in men compared to women within the population of patients diagnosed with colon cancer (3). However, several smaller-scale investigations have failed to establish a conclusive association between gender and the manifestation of metastases in mCRC (14,15). In the present study, 60% of the subjects were male and 40% were female, aligning with the existing literature findings.

Age. In Riihimaki's investigation, a correlation was observed between younger age (under 60 years old) and a heightened occurrence of bone metastases. Patients aged over 79 years exhibited an odds ratio for developing bone metastases of 0.4 in comparison to those under 60 years old (3). Typically, younger age is indicative of a more biologically aggressive disease profile (16). In our study, the median age of 65 years was consistent with findings reported in existing literature.

Primary tumor location. The prevalence of bone metastases was notably higher in the left colon (57.1%, n=20). A systematic review revealed an association between the distal localization of the primary tumor and the occurrence of bone metastases. Eight studies reported an elevated risk of

bone metastases development for tumors situated in the rectum (3, 5, 14, 15, 17-20), with an odds ratio (OR) of 1.5 according to Riihimaki's investigation (3). Additionally, Chiang *et al*. observed a heightened risk for distal rectal tumors compared to proximal rectal tumors (20). The underlying pathophysiological mechanism may be attributed to the presence of the Batson venous plexus, a network of valveless veins connecting the thoracic and deep pelvic veins to the internal vertebral venous system (21).

Other types of metastases. The study cohort predominantly exhibited peritoneal (26.5%), hepatic (26.5%), and pulmonary (5.7%) secondary lesions. In contrast to our findings, metastases to lymph nodes post-primary surgery and pulmonary metastases at any point were identified as potential risk factors for bone metastases development (22). All studies indicated an increased risk association between bone metastases and pulmonary metastases (19), with reported odds ratios ranging between 2.5-4.8 in patients with lung secondary lesions (10,14). While some studies suggested an association between liver metastases and bone metastases, the data remain inconclusive due to conflicting findings (23). Notably, our study reported a higher frequency of peritoneal metastases alongside bone metastases; however, it's essential to acknowledge the limited size of the study cohort, and statistical significance was not established in this context.

Primary tumor surgery. Remains a subject of ambiguity in mCRC management, often recommended for patients with advanced tumors causing symptomatic presentations (24). In our examined cohort, 51.4% of patients underwent primary tumor resection, indicating a significant proportion of cases with symptomatic and advanced tumors. Notably, conclusions regarding the potential association between T stage and the risk of bone metastases could not be definitively drawn. Sundermeyer's study suggested a correlation between early-stage tumors and bone metastases, while conflicting evidence from another study proposed an association between advanced tumors and bone metastases (19).

Regarding **pathological subtypes,** signet ring cell carcinoma demonstrates a potential association with increased susceptibility to bone metastases, although this relationship remains underexplored. Conversely, other histological subtypes do not seem to influence the likelihood of bone metastases (25). Two studies noted an association with the mucinous subtype among patients with metastases (23,26). However, in our investigation, information regarding tumor pathological subtypes was not available.

Degree of differentiation did not exhibit an association with bone metastases in our study. The majority of patients presented with moderately differentiated (G2) tumors, accounting for 73.5%. Although four studies did not identify associations with poorly differentiated tumors, high-grade tumors were linked to a shorter duration before the onset of bone metastases (7, 27).

KRAS, NRAS, and BRAF genetic mutations were detected in 37.1% (n=13) of patients, with NRAS and BRAF mutations each present in 2.8% (n=1) of patients. Hypotheses suggest that distinct molecular profiles of cancer may elucidate metastatic patterns, potentially increasing tumor propensity for seeding specific organs such as bone, brain, or lung. RAS mutations are recognized predictors of unfavorable responses to anti-EGFR treatment and are associated with aggressive biological profiles (28-30).

Of the mutations evaluated for association with bone metastases, only RAS mutations have been identified as potentially favorable factors, albeit with limited and conflicting evidence. Four studies investi-

gated the relationship between RAS mutations and bone metastases (18, 31, 32). Yaeger's study revealed a significant association between RAS mutations and bone metastases in multivariate analysis, reporting a hazard ratio (HR) of 1.62 (18,28). Kemeny *et al.* focused solely on KRAS mutations in exon 2 but observed a significant incidence of bone metastases in patients with mutations compared to wild type (28). Conversely, two other studies did not establish a significant association between RAS mutations and bone metastases (31,32).

The potential association between RAS mutations and bone metastases may arise from differential gene expression and protein activation, including variations in integrin expression between RAS wild-type and RAS-mutated colon cancer cells (33). Studies have suggested an organ-specific exosomal protein expression pattern influencing the creation of a premetastatic niche (34). Specifically, exosomal integrin has been implicated in directing metastatic dissemination to bone (35).

Treatment modalities for bone metastases have been documented in three studies, encompassing bisphosphonates, chemotherapy, radiotherapy, surgery, and analgesic therapy. The efficacy of bisphosphonates was statistically assessed across all three studies (5, 7, 36). However, the randomized trials were characterized by small sample sizes and divergent methodologies, yielding low-level evidence regarding the potential of bisphosphonates to delay adverse skeletal events such as pathological fractures, spinal cord compression, and the need for bone radiation therapy, as well as alterations in antineoplastic therapies and bone surgery. Notably, no significant impact on OS was observed (8). Denosumab's efficacy in CRC bone metastases remains unexplored, consistent with existing research on antiresorptive treatment effects in bone metastases of lung, breast, and prostate cancers, which have demonstrated a reduction in skeletal events. Investigations into the effects of other therapeutic modalities on CRC bone metastases have been limited. The impact of chemotherapy and radiotherapy on OS following bone metastases diagnosis was examined solely in a retrospective cohort study. Systemic chemotherapy demonstrated an improvement in OS in patients with bone metastases based on univariate analysis; however, it's noteworthy that the majority of patients also presented with visceral metastases, potentially influencing the observed increase in OS (37). In our study, a high majority of patients received FOLFOX or CAPEOX (85.6%) associated with Bevacizumab (77.1%).

Prognosis. In this study, the median OS was 17.3 months, with a PFS of 10.7 months, representing a superior outcome compared to the majority of previous investigations. Analysis of survival among patients with bone metastases was referenced in 16 studies, revealing a range of median OS durations from 5 to 21 months (8). Khattak and Riihimaki reported a median survival ranging between 5.1 and 5.5 months. Notably, various studies have explored the prognostic outlook of patients with bone metastases in comparison to those with metastases at alternate sites, yielding conflicting results. Khattak and Riihimaki observed that patients with mCRC and exclusive bone metastases exhibited shorter survival durations than those with metastases confined to a single site or affecting other sites such as the liver or lungs (38,39). In the same direction, Qui *et al.* identified a one-year OS rate of 29.6% for patients with bone-only metastases, compared to 60.2% for those with hepatic metastases and 60.2% for individuals with pulmonary metastases (17). Three additional studies reported a more favorable median survival for patients

with solitary bone metastases in comparison to those with concurrent bone and visceral metastases. Several prognostic variables were associated with an unfavorable prognosis, including osteolytic lesions, multiple bone lesions, metastases to the ribs, elevated levels of carcinoembryonic antigen (CEA), presence of other metastatic sites, pulmonary metastases, and bone metastases at initial diagnosis. Nonetheless, variations in study designs, cohorts, and inclusion of different variables rendered direct comparisons challenging. Furthermore, only a minority of studies incorporated multiple variables in their analyses across disparate datasets (7, 40, 41).

In our study, in multivariate analysis for OS, anti-EGFR treatment demonstrated a positive association with increased survival of 17.6 months. Although patients with left-sided mCRC may derive benefits from chemotherapy and anti-EGFR treatment compared to Bevacizumab as first-line therapy, the differences observed in randomized clinical trials were typically around 3 to 7 months (42-44). It is probable that due to the small sample size in our study, these survival benefits were amplified; however, they should be considered more as a point for further hypothesis within this patient subset. Conversely, peritoneal metastases and NRAS mutation emerged as negative prognostic factors for survival, leading to reductions of 1.7 months and 5.8 months, respectively. Notably, these prognostic factors were not previously associated with survival in patients with CRC and bone metastases according to existing literature. Therefore, these findings represent a novel contribution, first described in our study for patients with CRC and bone metastases.

Study limitations. The conducted study provides insights into the clinical, pathological, and molecular characteristics of patients with CRC and bone metastases, along with certain prognostic factors. However, it is crucial to interpret the presented information cautiously as this is a retrospective, single-center study with a small sample size and limited statistical power. Nevertheless, it offers preliminary data regarding this patient subset within a population from Romania for the first time and could serve as a foundational framework for further investigation in prospective, multicenter studies on this topic.

CONCLUSIONS

We investigated the clinical, pathological, and molecular characteristics of a highly rare subset of patients, specifically those diagnosed with mCRC presenting with bone metastases and treated at a tertiary center in Northeast Romania. Subsequently, the observed incidence of bone metastases stood at 10.5%, with a median age of onset being 65 years. These metastases displayed a higher prevalence among males, with primary tumors predominantly localized in the left colon. Tumors were frequently classified as grade 2 differentiation (G2), with KRAS mutations being the most prevalent, while NRAS and BRAF mutations were exceedingly rare occurrences. Patients exhibited worse PFS and OS compared to those described in the literature for other metastatic sites. Among the identified prognostic factors, anti-EGFR treatment was associated with a favorable outcome, while the presence of peritoneal metastases and NRAS mutation were indicative of a poorer prognosis.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest. This article was co-funded from the European Social Fund - the Human Capital Operational Programme, Project/ Grant No: POCU/993/6/13/154722. ANTIBIOTIC USE AMONG PATIENTS WITH ACUTE EXACERBATION OF COPD IN PULMONARY DISEASES UNIVERSITY CLINICAL HOSPITAL FROM NORTH-EASTERN ROMANIA (Abstract): **Aims:** Acute exacerbations of Chronic Obstructive Pulmonary Disease (AECOPD) need sometimes hospitalizations and requires five to seven days of oral antibiotics, according to GOLD recommendations. The aim of our study was to find out the most common used antibiotics in patients with AECOPD admitted in a University Clinical Hospital of Pulmonary Diseases from North-Eastern Romania, from June 2014 to May 2019. **Materials and methods:** A descriptive cross-sectional, single-center, retrospective study, conducted among 460 admissions in hospital with J44.0 (COPD with lower airway acute infection) and J44.1 (COPD with acute, nonspecific exacerbation) diagnostics. **Results:** The majority (354; 77%) of admissions were for male; average age was 66 ± 9 years. The preferred antibiotic for first use was ceftriaxone (51%), but the patients were treated also with ciprofloxacin (13%), levofloxacin (12%), ceftazidime, amoxicillin + clavulanic acid or other antibiotics according to antibiograms, with a medium of 10 days treatment. Most of the patients received one antibiotic during hospitalization, 23.9% received two antibiotics and 7.6% of patients received 3 antibiotics. Hospitalization average length was 11 ± 5 days. **Conclusions:** Ceftriaxone was the preferred drug for acute COPD exacerbation treatment for hospitalized patients, while the average hospital length in our study was 11 days. **Keywords**: ANTIBIOTIC USE, ACUTE EXACERBATIONS OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE, LENGTH OF HOSPITAL STAY.

INTRODUCTION

Antimicrobial chemotherapy choice is a challenge in patients with Chronic Obstructive Pulmonary Disease (COPD), due to both bacterial and viral causes of acute exacerbation. COPD, one important cause of mortality and morbidity worldwide (1), had a hospital in-patient admission rate of 4.70% in Romania in 2017. The most frequent bacteria causing infections in COPD patients are *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Pseudomonas aeruginosa*, but other bacteria such as Enterobacteriaceae and *Chlamydia pneumoni-*

ae might also be involved (2). Acute exacerbations of COPD (AECOPD) need sometimes hospitalizations and have socio-economic impact through severe deterioration of general health status, the progression to complications of disease, and increase use of antibiotic consumption (3-5).

COPD exacerbations require five to seven days of oral antibiotics, according to GOLD recommendations. The initial therapy of AECOPD is with an association of aminopenicillins and clavulanic acid, tetracyclines (doxycycline) or macrolides (azithromycin), in selected patients quinolone (5) and identification of the bacteria and antibiogram are needed. A judicious use of antibiotics administration for AECOPD decreases the risk of treatment failure and early relapse.

There are very few studies on the use of antibiotics in AECOPD in North-East Romania, therefore the aim of our study was to find out the most common used antibiotics in patients with AECOPD admitted in a University Clinical Hospital of Pulmonary Diseases from North-Eastern Romania, from June 2014 to May 2019.

MATERIALS AND METHODS

Study design

This is a descriptive cross-sectional, single-center, retrospective study, conducted in Iasi University Clinical Hospital of Pulmonary Diseases from North-Eastern Romania (340 beds- adult and pediatric pulmonology, thoracic surgery and intensive care). The study received the approval from the Ethics Committee of "Grigore T. Popa" University of Medicine and Pharmacy from Iasi, Romania, and the Ethics Committee of Clinical Hospital of Pulmonary Diseases of Iasi, Romania (approval date 04.06.2020, respectively 22.01.2021).

The inclusion criteria were: 1) Patients of more than 40 years, with diagnosis of COPD, based on spirometry (with the ratio post-bronchodilator forced expiratory volume in one second (FEV1)/ forced vital capacity (FVC) < 0.70),admitted in the hospital, 2) specific J44diagnosis codes of COPD established by International Classification of Diseases 10thRevision (ICD-10): J44.0 - COPD with lower airway acute infection, J44.1 - COPD with acute, nonspecific exacerbation; 3) more than 24 h of hospital length; 4)received at least one antibiotic during hospitalization. There were excluded: patients admitted to the intensive care unit (ICU), other chronic pulmonary diseases (asthma, pulmonary interstitial disease, and pulmonary embolism), any type of cancer disease, tuberculosis under treatment and incomplete data in clinical record file.

There were extracted the following data from electronic and paper medical clinical record files: date of admission and discharge from hospital, length of hospitalization, age, gender, administered antibiotics, bacterial pathogen from antibiogram.

Data Analysis

Results are presented as mean ± standard deviation (SD) for continuous variables and as absolute values and percentages for categorical variables.

RESULTS

A total of 460 admissions in hospital with J44.0 - COPD with lower airway acute infection and J44.1 - COPD with acute, nonspecific exacerbation, were included. They were 354 (77%) admissions for male and 106 (23%) admissions for female. The age of patients varied from 44 years to 88 years, average age was66 ±9 years.

The patients were treated with ceftriaxone, ciprofloxacin, levofloxacin, ceftazidime, amoxicillin + clavulanic acid or cefuroxime according to antibiograms, with a medium of 10 days treatment. In COPD

patients most of the time treatment was started with cephalosporins, rarely with amino-penicillins. Other antibiotic that was recommended in small proportion were clarithromycin, gentamicin, clindamycin, trimethoprim/sulfamethoxazole. The preferred antibiotic for first use was ceftriaxone (fig. 1). Most of the patients received one antibiotic during hospitalization, 23.9% received two antibiotics and 7.6% of patients received 3 antibiotics; the predominant route was intravenous. The predominant bacteria in the sputum were Gram Negative bacteria, followed by *Streptococcus spp.*, while MRSA (methicillin resistant *Staphylococcus aureus*) bacteria was not detected.

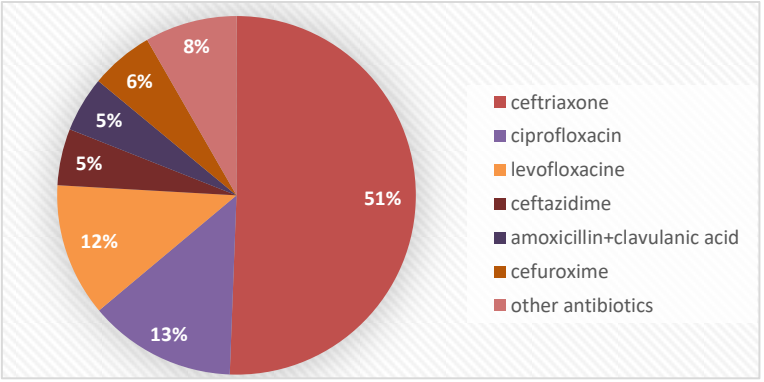

Fig. 1. Patients antibiotic therapy during hospitalization.

Trend of antibiotic use, depending on trimesters and year are depicted in figure 2. There was a higher use of ceftriaxone and ciprofloxacin in the third trimester of 2015.

Hospitalization average length was 11 ± 5 days (fig. 3), the longest duration of hospital stay being of 38 days due to comorbidities. Most of length of hospital stay was in the category of mid-stay: 60 brief-stay (2-6 days), 396 mid-stay (7-30 days) and 4 long-stay (>31 days).

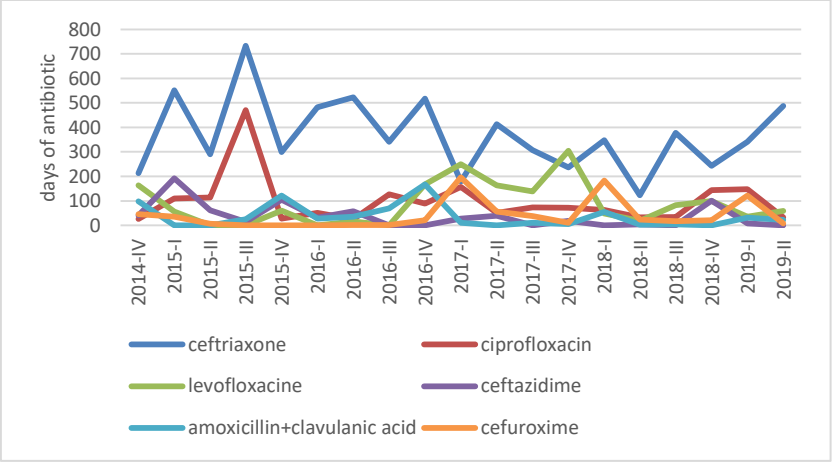

Fig. 2. Trend of antibiotic use (days of antibiotic).

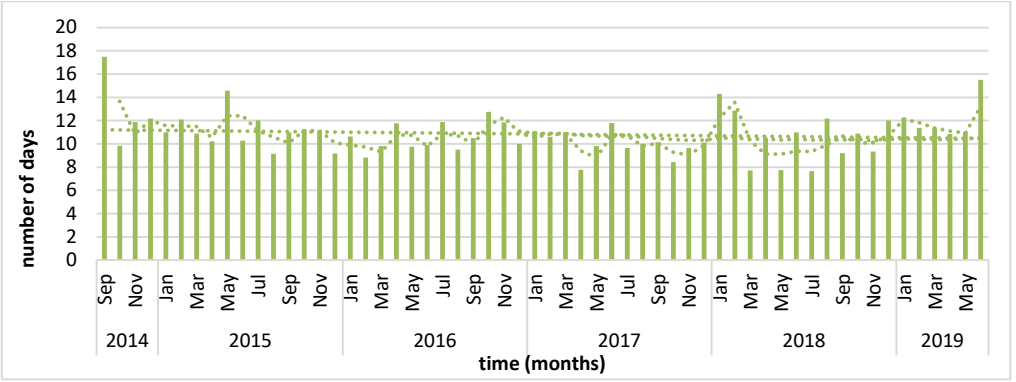

Fig. 3. Average of hospital day length (days)

DISCUSSION

Our findings showed that the preferred antibiotic to be used in COPD patients was ceftriaxone, followed by ciprofloxacin or levofloxacin. According to GOLD recommendations, the preferred route of administration is oral, but the intravenous and the duration of therapy can be longer in COPD exacerbations admitted in hospital. The choice of antibiotic should take into consideration also the local hospital/ region antimicrobial resistance map (5). The European Respiratory Society and the American Thoracic Society guidelines from 2017 recommend beta-lactams in COPD exacerbations to reduce the risk of treatment failure and increase the time between exacerbations according to local hospital guidelines and because the risk of co-infections are frequently reported with the increase in the severity of COPD (5, 6). The use of antibiotics during hospital stay reduce the risk of readmissions and the risk of mortality (7-10).

According to 2020 evaluation of World Health Organization, death due to COPD was on the third place among global death causes (6% of total deaths), due to comorbidities that lead to frequent exacerbations with or without hospitalizations (3). Data obtained from larger cohort might give details on difference on gender or smoking as factors that influence hospitalization length. A recent study on AECOPD inpatients, found that females and males had similar in-hospital and long-term survival and that female smokers had significantly worse outcomes (7).

The use of macrolides in our study was low, even macrolides might be recommended as an adjunctive treatment AECOPD. Since this practice becomes increasingly common, there are studies that found the importance to monitor its benefits on AECOPD, the adverse events and antimicrobial resistance patterns (11).

The average hospital length in our study was 11 days, which is longer in contrast to a cohort study where the mean was 6-7 days in AECOPD patients (12), but among the values from studies that mention a variable average of the length of stay for AECOPD, ranging from 5 to 12 days (13, 14).

Limitations of the study

There are some limitations in our study: it was a single center study with a small number of hospitalized COPD patients; therefore, our findings might not be generalized.

CONCLUSIONS

Ceftriaxone was the preferred drug for AECOPD treatment for hospitalized patients, followed by quinolones (ciprofloxacin or

levofloxacin), while the average hospital length in our study was 11 days. It is difficult to differentiate between bacterial or viral cause of infection; therefore, clinicians are tempted to recommend antibiotics, that might lead to overuse of antibiotics.

CONFLICT OF INTEREST AND FUNDING

The authors declare no conflict of interest.

This research was co-funded from the PhD doctoral program, from European Social Fund - the Human Capital Operational Program, Project/Grant No: POCU/993/6/ 13/154722.

ACKNOWLEDGMENTS

The authors thank Marius Mihail Cretu for data analysis.

PRELIMINARY DATA ON THE LINK BETWEEN THE INTESTINAL MICROBIOME AND AUTISM SPECTRUM DISORDERS (Abstract): Today autism is an extremely serious problem. Although the number of the children born with this pervasive developmental disorder has increased, the causes of its occurrence have not yet been identified. **Aim:** We want to demonstrate that the severity of gastrointestinal disorders would be related to the worsening of symptoms in people diagnosed with autism spectrum disorders (ASD). Analyzing the intestinal microbiome is particularly important for people with autism because an imbalance in the intestinal microbiome affects their good physical and mental development. **Materials and methods:** In our study, we highlighted the importance of a suitable diet for a better development of children with autism. Children with ASD are at a significantly increased risk of chronic gastrointestinal problems from an early age. The underlying mechanism to explain how gastrointestinal dysfunction can affect autism spectrum disorder behaviors has led to the idea that the microbiome-gut-brain axis contributes to behavioral and cognitive disorders. **Results:** These children have a high prevalence of intestinal transit disorders such as constipation, a fact that influences the severity of symptoms in ASD. The results of our research indicate an increased prevalence of gastrointestinal symptoms among children with ASD compared to the control group. **Conclusions:** Intestinal dysbiosis can influence the severity of symptoms in autism. An understanding of the mechanisms by which the microbiome-gut-brain axis acts will lead to the use of therapeutic strategies. **Keywords:** INTESTINAL MICROBIOME, DYSBIOSIS, AUTISM SPECTRUM DISORDERS.

The specificity of children with autism spectrum disorders (ASD) is the way in which they manifest behaviorally, the withdrawal from social life or even from reality, but also the fact that autism affects such young and innocent children, depriving them of the opportunity to enjoy life. The development of children with autism, later of adults, is affected by this isolation from the environment in which they live. Although these people live in society and have families, they fail to integrate properly. The destructive character of autism is mainly the detachment from the social environment. Fecal analysis can provide clues about intestinal microbial metabolism. However, most studies focus on metabolites in urine and blood. Only a few studies have examined the gut microbiota and the metabolic products of the microbiota and attempted to correlate them with ASD. Wang *et al*. have observed increased concentrations of short-chain fatty acids (SCFA) and ammonia in the feces of children with ASD (1). The gut microbiota plays an essential role in human health and in various disorders such as ASD. A growing body of preclinical research suggests that gut dysbiosis may influence brain function and social behavior, but little is known about the mechanisms underlying these interrelationships and how they may influence pathogenesis or severity in ASD (2). In their research, Angelis *et al.* reported a decrease in total SCFA in children with ASD (3). They also observed altered levels of the neurotransmitter's glutamate and GABA in feces samples. Glutamate was highest among children with autism and GABA was lowest among children with pervasive developmental disorder not otherwise specified (PDD-NOS). In addition, phenolics, including p-cresol, were higher in fecal samples from children with autism and PDD-NOS, but phenolic and p-cresol levels were similar between children with ASD and children from control group (3). ASD patients with gastrointestinal symptoms have changes in microbial composition that are likely related to digestive enzyme deficiencies, carbohydrate malabsorption, selective eating, bacterial toxins, serotonin metabolism, and inflammation (4). The high prevalence of gastrointestinal disorders among ASD patients has led researchers to consider the gut microbiota as a possible factor in the pathogenesis of ASD. Thus, many studies have linked gut dysbiosis, which is frequently observed in patients with autism spectrum disorders, to the modulation of brain function and social behavior, but little is known about this relationship and contribution to the etiology of ASD (5, 6, 7). Hill *et al*. noted that people with ASD prefer energy-dense, nutrient-deficient foods and reject fruits, vegetables, and whole grains (8). The introduction of a new food or physical activity can often cause disruptive behavior that ultimately leads parents to give in to their children's demands (9). Therefore, new foods should be introduced to these children gradually to ensure familiarity with the taste and texture of the food (10).

Parents should teach babies good eating habits from the time the babies start to eat solid food. Autism spectrum disorders can have various social implications, both for people diagnosed with this developmental disorder, as well as for their families and society in general. The literature reports that parents of these children experience increased psychological distresses, including depression, anxiety, interpersonal sensitivity, hostility, schizoid traits, paranoia, and schizophrenia (11). Stressors relate to both

family and social life and include the emotional aspects of a disabled child, understanding the child's needs, various aspects of primary care, medical and educational services, and financial difficulties (12,13).

Due to the high incidence of ASD, as well as the large number of medical services that affected children need, the impact of ASD on the family and the state budget becomes increasingly important. Financial resources allow services to be planned, resources to be allocated and policies to be modified accordingly (14). Medical costs for children with ASD average 3 to 9 times higher than for other children (15).

Therefore, further elucidation of microbiota composition will provide a novel and promising therapeutic approach to control or prevent symptomatology exacerbation in autism. There is growing evidence that the microbiota-gut-brain axis can influence gastrointestinal health and modify those behaviors associated with ASD. Gut microbiota and the metabolic products of microbial populations may be linked not only to gastrointestinal problems but also to behavioral symptoms in autism. In particular, we focus on how gut dysbiosis may affect intestinal epithelial permeability, immune function and microbial metabolites in individuals with autism. To better understand the structure of the gut microbiota in children with autism spectrum disorders of different ages, as well as the relationship between the gut microbiota and fecal metabolites, we need to assess the gut microbial population.

The purpose of this research is to identify if there are significant differences between the intestinal microbiome analysis in the case of children with ASD compared to the control group consisting of neurotypical children.

MATERIALS AND METHODS

We aimed to identify if there is a causal link between intestinal transit disorders such as chronic constipation, the increased level of psychomotor agitation, frequent colds and the presence of an imbalance in the intestinal microbiome bioindicators. We also wanted to observe if there are differences between the values of bioindicators from the intestinal microbiome obtained by the participants from the two research groups.

Objectives

O1. Carrying out the analysis of the microbiome from fecal matter in subjects with ASD and those in the control group.

O2. Establishing how the intestinal imbalance influences the severity of symptoms.

O3. Identification the sort of enterotype of the research participants.

Hypotheses

HS1.It is assumed that there are statistically significant differences between the results of bioindicators from the intestinal microbiome in children with ASD and in neurotypical children.

Hs2. It is assumed that the presence of transit disorders such as constipation can be a cause of imbalances in the intestinal microbiome.

Hs3. It is assumed that the disturbance of the profile of intestinal bacteria can influence the behavioral manifestations.

Ethics approval. In order to participate in this research, the parents of children with ASD and those in the control group have signed a consent agreement.

Study participants. A number of 16 children have participated in this study, 8 of whom have been diagnosed with ASD,

have an increased psychomotor agitation, frequently catch colds due to low immunity and have intestinal transit disorders such as constipation, and 8 are children without disabilities. The children from the first group have been diagnosed with infantile autism and severe developmental delay before the age of 3 and have started psychological and speech therapy immediately after diagnosis at the Psychological Centers in the city of Constanţa.

The ages of the participants in this study are between 3 and 17 years. The groups are similar in terms of age and gender and all live in Constanţa.

Inclusion and exclusion criteria

Group 1. ***Inclusion criteria:*** diagnosis of ASD; informed consent signed by the parents; constipation – defined as the condition of eliminating bowel contents with a frequency less than 3 stools per week (16); increased psychomotor agitation; frequent colds due to low immunity. ***Exclusion criteria***: absence of autism diagnosis; lack of transit disorders; absence of consent agreement.

Group 2. ***Inclusion criteria:*** children without disabilities; informed consent signed by the parents. ***Exclusion criteria:*** presence of ASD diagnosis; absence of consent agreement.

Methods. The participants from both groups have been analyzed for the microbiome from fecal matter, analysis carried out at the *Bioclinica laboratories*.

All the data obtained from the analysis of the bioindicators of the intestinal microbiome were statistically analyzed with the *SPSS version 24 program*. The statistical results will be presented in the tables of the paper.

RESULTS

Enterotypes distribution

In group 1, four participants (50%) had enterotype 1, two participants (25%) had undetermined enterotype, one participant (13%) had enterotype 2 and one participant (13%)had enterotype 3 (fig. 1). In group 2, all eight subjects (100%) had enterotype 1 (fig. 2).

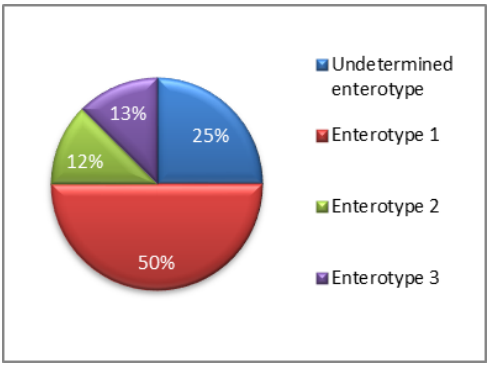

Fig. 1. Distribution of enterotypes group 1

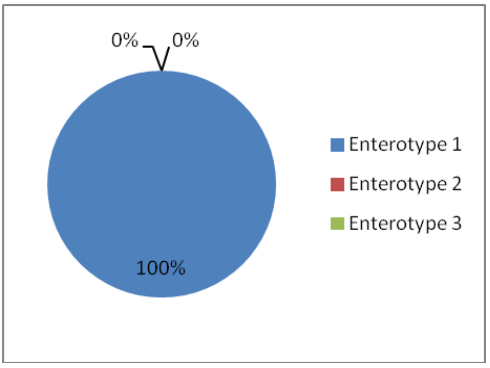

Fig. 2. Distribution of enterotypes group 2

Bioindicators analysis

Fecal pH

In group 1, three participants (38%) had high values, and five participants (62%) presented normal values (fig. 3). None of the participants had low values. In group 2, one participant (13%) had high value, seven participants (87%) had normal values. None of

the subjects presented low values (fig. 4).

Biodiversity (Shannon index)

In group 1, five participants (62%) had low values, three participants (38%) had normal values, while none of the participants presented high values (fig. 5). In group 2, seven participants (87%) had normal values, one participant (13%) had high values, while none of the subjects presented low values (fig. 6).

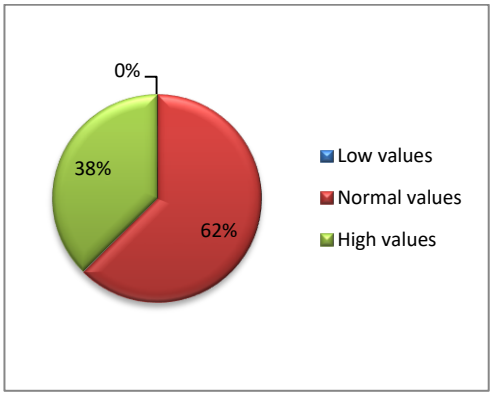

Fig. 3. Fecal pH – group 1

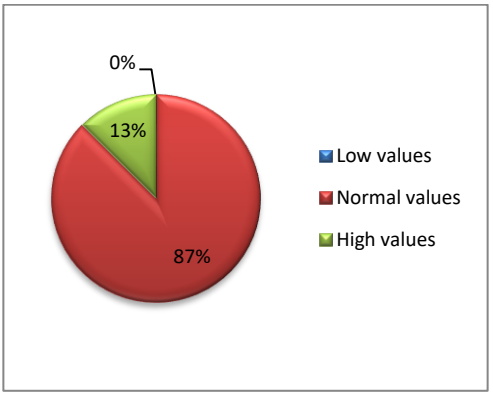

Fig. 4. Fecal pH – group 2

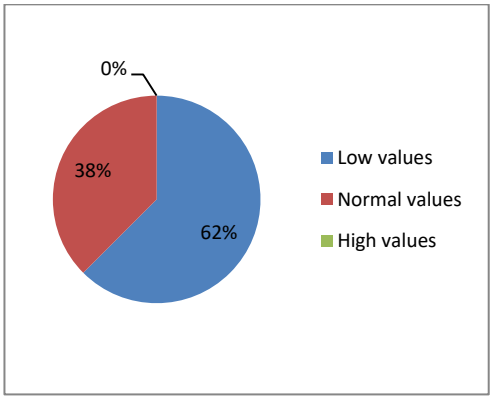

Fig. 5. Biodiversity (Shannon index) group 1

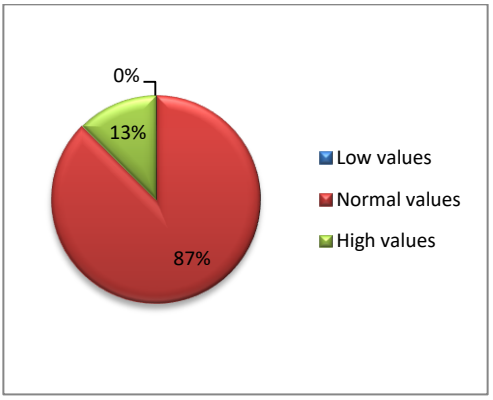

Fig. 6. Biodiversity (Shannon index) group 2

Firmicutes/Bacteroidetes Report

All the participants in group 1 and 2 had normal values.

Butyrate production

In group 1, two participants (25%) had low values, while six participants (75%) had normal values (fig. 7). In group 2, seven participants (87%) had normal values, and one participant (13%) had high values (fig. 8).

Lactate production. In group 1, four participants (50%) had normal values, while the other four (50%) had low values (fig. 9). In group 2, six patients (25%) had normal values, while two subjects (25%) presented high values (fig. 10).

Acetate production. In group 1, five patients (62%) had normal values, while three patients (38%) had high values (fig. 11). In group 2, all subjects had normal values (fig. 12).

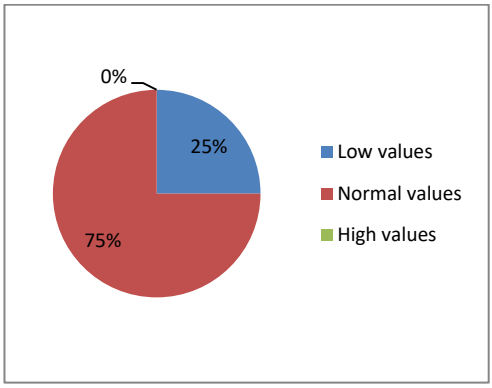

Fig.7. Butyrate production – group 1

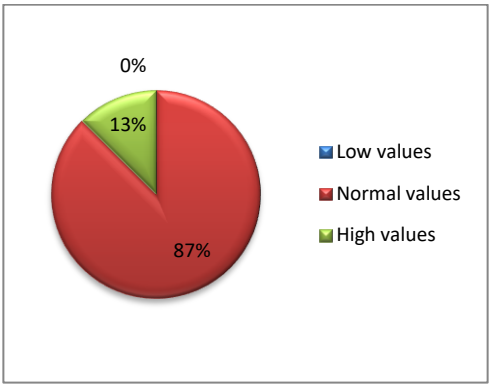

Fig. 8. Butyrate production – group 2

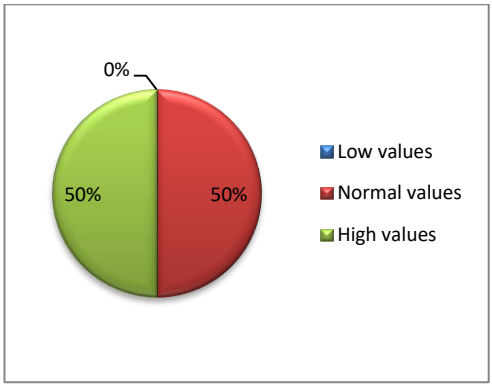

Fig. 9. Lactate production - group 1

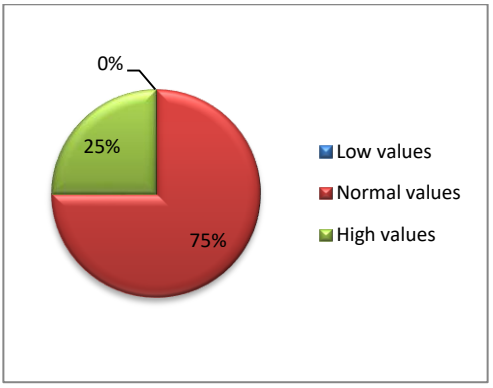

Fig. 10. Lactate production – group 2

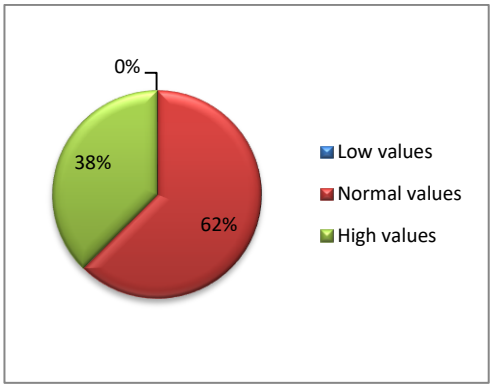

Fig. 11. Acetate production – group 1

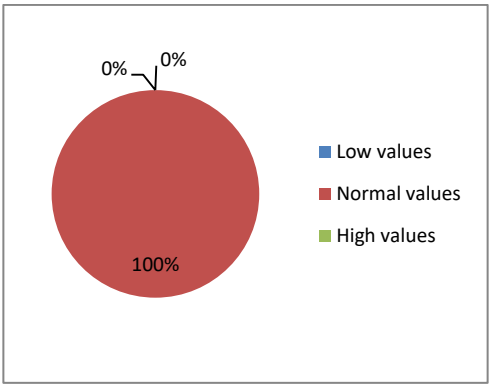

Fig. 12. Acetate production – group 2

Mucin degradation. In group 1, one patient (12%) had low values, six participants (75%) had normal values, while one participant (13%) had high values (fig. 13). In group 2, seven subjects (87%) had normal values, and one (13%) had low value (fig. 14).

Lipopolysaccharide (LPS)-positive bacteria

In group 1, four participants (50%) had normal values, while other four (50%) had high values (fig. 15). In group 2, seven subjects (87%) had normal values, while one (13%) had high values (fig. 16).

Statistics

To test the normality of the distribution, we will apply the Kolmogorov-Smirnov test and the Shapiro-Wilk test and we will interpret the results according to the statistical significance. Conform to the results obtained by the goup 1 in the Kolmogorov-Smirnov test we have an abnormal distribution for Lactate production because $p = 0.001 < 0.05$, for Mucin degradation $p = 0.007 < 0.05$, for Butyrate production $p = 0.001 < 0.05$, and for the rest of the bioindicators the distribution is normal because $p > 0.05$. In the case of the Shapiro–Wilk test, we have an abnormal distribution for Lactate production because $p = 0.004 < 0.05$, for Mucin degradation $p = 0.006 < 0.05$, for Butyrate production $p = 0.003 < 0.05$, and for the rest of the bioindicators the distribution is normal. Since we have a small number of participants, the Shapiro–Wilk test is relevant (tab. I).

Firmicutes/Bacteroidetes Report	.162	8	.200*	.897	8	.274
Biodiversity (Shannon index)	.256	8	.130	.886	8	.213
*. This is a lower bound of the true significance. a. Lilliefors Significance Correction						

In the case of Kolmogorov-Smirnov test for second group we have an abnormal distribution for Lactate Production because $p = 0.000 < 0.05$ and for the rest of the bioindicators the distribution is normal because $p > 0.05$. In the case of the Shapiro-Wilk test, we have an abnormal distribution for Lactate production because $p = 0.000 < 0.05$, and for the rest of the bioindicators, the distribution is normal because $p > 0.05$. Since we have a small number of participants, the Shapiro–Wilk test is relevant (tab. II).

After analyzing the Shapiro-Wilk normality test from both groups, we notice that we have a normal distribution for: Acetate production, LPS-positive bacteria, Faecal Ph, Shannon Biodiversity and Firmicutes/Bacteroidetes report and in the case of bioindicators: Lactate production, Mucin degradation and Butyrate production we have an abnormal distribution.

*. This is a lower bound of the true significance. a. Lilliefors Significance Correction						

We will apply the T test in the case of bioindicators with normal distribution and the non-parametric Wilcoxon test in the case of abnormal distribution.

The descriptive statistics of the T test includes the statistical indicators Mean, Standard Deviation and Standard Error Mean (tab. III).

TABLE III.

T-test between group 1 and group 2

Group Statistics					
	Lot	No	Mean	Std. Deviation	Std. Error Mean
Fecal pH	1	8	6.375	.4432	.1567
	2	8	6.500	.3780	.1336

The Independent Samples Test compares differences in means of two independent groups in order to determine whether there is statistical evidence that the associated population means are significantly different. The Independent Samples Test is a parametric test (tab. IV).

Levene's subtest is applied to verify homogeneity of variance. The homogeneity of the variance is a basic condition of the T-test. We observe that $p > 0.05$ for all the values of the bioindicators, so the homogeneity of the variance is verified.

In the T-test, all values of $p > 0.05$, so there are no statistically significant differences between the two groups. The same thing can be observed from the values of t are small.

The effect size in the Independent T-test shows how strong are the differences between the groups. The values smaller than 0,20 indicates that the effect size is weak, the values situated between 0,20 and 0,60 indicate that size effect is medium, and the values bigger than 0.60 indicates that the effect size is strong.

For the bioindicators Fecal pH and Biodiversity (Shannon index) we have a medium effect size, in case of LPS-positive bacteria and Acetate production we have a strong effect side and for Firmicutes/Bacteroidetes Report we have a weak effect size (tab. V).

The non-parametric Wilcoxon test is a statistical test that compares two paired groups. The tests essentially calculate the difference between sets of pairs and analyze these differences to establish if they are statistically significantly different from one another. For Mucin degradation it can be seen that $p = 0.208 > 0.05$, so we have no statistical significance between the two groups and the null hypothesis will be retained (tab. VI).

TABLE IV.

Independent Samples Test

Independent Samples Test											
		Levene's Test for Equality of Variances		t-test for Equality of Means							
		F	Sig.	t	df	Significance		Mean Difference	Std. Error Difference	95% CI of the Difference

DISCUSSION

Because the children from different racial, socioeconomic, and ethnic backgrounds are affected by ASD and because of the high prevalence of ASD in the world, many of the problems associated with ASD cause challenges for society as a whole. Establishing the diagnosis before the age of two and starting psychological and communication therapy help to create quality and can significantly reduce the symptoms associated with autism, due to the plasticity of the brain, which is a characteristic of the early period of development. Balancing the body, especially from a biochemical point of view, can increase the chances of symptom relief and, implicitly, of improving the general state of health. In both groups there are children who present imbalances at the level of the microbiome. This may be influenced by diet and cause further research focusing on the link between diet and the microbiome.

Using a diet, specific nutrients im-

portant for making learning more efficient and increasing social integration cannot be missing. Children with autism spectrum disorder tend to have a limited food repertoire and a greater reluctance to eat food than neurotypical children. Modulation of the gut microbiota in individuals with ASD and gastrointestinal disorders appears to be a promising future medical target. A probiotic approach should act as a means of restoring a healthy microbiota in addition to reducing gut permeability. To confirm the efficiency of probiotic therapy in children with autism spectrum disorders, larger studies with laboratory analyzes of the microbiota are needed for better direction. Further research on the brain-gut-microbiome axis may lead to new methods of identifying gastrointestinal disorders in children with autism spectrum disorders and new treatments for autism spectrum disorder behavior.

Diet plays an important role in determining gut microbial composition and function; therefore, a selective diet can influence the gut microbial community. Overall, the approach to autism needs to be one based on respect, inclusion and support for people with autism and their families. By promoting awareness, understanding and acceptance, we can help create a more inclusive and supportive society for all its members.

CONCLUSIONS

Our research aimed to identify if there is a causal link between intestinal transit disorders such as chronic constipation, the increased level of psychomotor agitation, frequent colds and the presence of an imbalance in the intestinal microbiome bioindicators. After analyzing the values obtained for the bioindicators from the intestinal microbiome, we notice that all the participants in group 1 have values different from the normal ones for at least 1 analyzed indicator, and in the case of group 2, we note that a number of 4 participants have all normal values, and the other 4 participants have at least one value different from the normal one. It can be observed, following the statistical interpretation of the results from test T, that there are no statistically significant differences in terms of microbiome analysis between the two groups participating in the research, $p > 0.05$, a fact that refutes hypothesis 1, namely: *it is assumed that there are statistically significant differences between the results of bioindicators from the intestinal microbiome in children with ASD and in neurotypical children.*

Regarding the connection between constipation and the imbalance at the level of the microbiome, it can be observed that the participants from group 1 present more imbalances at the level of the intestinal microbiome than the participants from group 2, which shows us that hypothesis 2 is confirmed, namely: *it is assumed that the presence of transit disorders such as constipation can be a cause of imbalances in the intestinal microbiome.*

For hypothesis 3, it can be observed, after analyzing the data, that there is a close connection between the problems arising at the level of bioindicators of the intestinal microbiome and the increased psychomotor agitation present in the study participants from group 1, so the hypothesis is thus confirmed, namely: *it is assumed that the disturbance of the profile of intestinal bacteria can influence behavioral manifestations*.

For group 1, we notice that we have a percentage of 75% of participants with enterotype 1 and for group 2 we have a percentage of 100%, that is all participants, with enterotype 1. After the laboratory

analysis, the enterotype of each participant has been identified. In two of the children with ASD, those who are 3 years old, enterotype determination could not be performed, probably due to their young age. We recommend consulting a pediatric gastroenterologist for the implementation of microbiota-targeted therapies, such as probiotics, prebiotics, food supplements. New insights into potential therapeutic interventions that can be used to reduce and treat symptoms associated with autism spectrum disorders can be mentioned.

Our research has showed that people with ASD that have severe symptoms and also transit disorders such as constipation, have an imbalance in the intestinal microbiome.

EDITORIAL

ESOPHAGEAL SURGERY AT THE CROSSROADS - PAST, PRESENT AND PERSPECTIVES - MINIMALLY INVASIVE ESOPHAGECTOMY

If the first author of the editorial represents the past (and perhaps the present), of this difficult type of surgery, the other author (Dr. Florin Achim, university Assistant Professor in the clinic), represents the future of this niche surgery, benefiting from a doctorate with the theme "Minimally invasive surgery of esophageal cancer", with serious training fellowships working directly with the greatest esophageal surgeons in Germany (Professor Arnulf H. Hölscher and Professor Karl-Hermann Fuchs - Fellowship Grant of The European Association of Endoscopic Surgery(EAES) in Klinik für Allgemein- Viszeral-, und Thoraxchirurgie Agaplesion Markus-Krankenhaus, Frankfurt am Main) with another fellowship in Dublin (Ireland) in St. James Hospital under Professor John Reynolds (President of the European Society of Diseases of the Esophagus-ESDE).

He recently completed a 3-month fellowship in a minimally invasive esophageal cancer surgery under Professor Koji Otsuka and Professor Haruhiro Inoue at the Esophageal Cancer Center, Showa University Hospital and Koto Toyosu Hospital, Tokyo, Japan; not to mention that he is also a promoter of minimally invasive esophageal surgery in our clinic. On the initiative of Dr. Florin Achim, a collaboration agreement was established between the Showa University Faculty of Medicine and the "Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania, a partnership that will benefit future generations of students, residents, young specialists and other researchers.

One of the most difficult esophageal pathologies to treat, esophageal cancer, currently benefits from a much more effective treatment through the multidisciplinary approach and the creation of centers of excellence with a high volume of esophageal pathology. Advances in staging, surgical technology, neoadjuvant therapy, and perioperative care have resulted in reduced morbidity and mortality. The current mainstay of curative treatment for localized disease is surgery, combined with neoadjuvant chemoradiotherapy for locally advanced stages.

The development of esophagectomy techniques initially went through two periods: that of the safety of the procedure, that of radicality, and currently it is in a new era of the minimally invasive approach that ensures a better quality of life for the patient.

To reduce postoperative morbidity, minimally invasive surgical techniques were introduced 32 years ago into the therapeutic arsenal of esophageal cancer. However, there are controversies related to the use of the minimally invasive approach in practice because it requires a demanding and difficult to access technical base, a laborious operative technique and has a long learning curve.

The first thoracoscopic esophagectomy was performed by Sir Alfred Cuschieri in 1992 (fig. 1) (1). Considering the high degree of complexity of minimally invasive esophagectomy (MIE) with esophageal reconstruction, 10 years followed in which the technique was viewed with reluctance by

teams of esophageal surgeons. At the same time, it was also a period of the beginning of the centralization of esophageal cancer cases, the results obtained by the specialists were good and many centers were not interested in introducing a new technique. Also, the immediate postoperative results were initially not up to expectations. Apart from a faster postoperative recovery and a lower rate of pulmonary complications, the minimally invasive esophagectomy failed to drastically influence the postoperative results. There were controversies in the literature regarding the quality of oncological resection.

Fig. 1. Sir Alfred Cuschieri

The results were also difficult to interpret due to the different types of approach used in the treatment of esophageal cancer and the complications associated with esophageal reconstruction. The imposition of minimally invasive techniques as standard treatment has come a long way in a difficult surgery like esophageal surgery, where excellence is achieved after a lifetime. Randomized clinical trials have confirmed the feasibility of minimally invasive esophagectomy, its role in reducing postoperative complications, especially pulmonary ones, and obtaining oncological results similar to the classic technique.

Surgeons familiar with video-assisted techniques continued to perform the operation observing a much better quality of life of the patients in the immediate postoperative period. All variants of the classic esophagectomy were reproduced through a minimally invasive approach including assisted by the da Vinci robot (RAMIE).

The minimally invasive esophagectomy was initially performed through a hybrid approach in several variants: thoracoscopic esophagectomy with laparotomy, *video-assisted thoracoscopic esophagectomy (VATE)* with laparotomy, laparoscopic mobilization of the stomach with right thoracotomy or thoracoscopic esophagectomy with manual assisted laparoscopic mobilization of the stomach (*hand-assisted laparoscopy*).

The first transhiatal esophagectomy through laparoscopic approach was performed by De Paula Al. in 1995 (2). Pneumoperitoneum facilitates the mediastinal transhiatal dissection, the direct esophageal branches of the aorta that are clearly identified and clipped, thus reducing bleeding risk. The thoracic duct can be viewed and clipped, reducing the risk of chylothorax.

Luketich has used minimally invasive esophagectomy in the treatment of the resected esophageal cancer in over 1,000 patients and found that the minimally invasive approach has appropriate results to the open esophagectomy according to the oncological resectability (3).

Watson DI improves the technique described by Ivor Lewis by introducing the minimally invasive approach (4). The technique allows an excellent view in both operative stages, the ability to perform lymphadenectomy on two fields and the avoidance of neck dissection of the esophagus in the 3-stage McKeown approach, with all the risks included, for example, the stenosis of the

esophagus anastomosis, the cervical anastomotic leakage or the injury of the recurrent left nerve (5).

Minimally invasive esophagectomy by 2-stage Ivor Lewis modified laparoscopic and thoracoscopic is a safe technique that has already passed the time trial and is effective in the surgical treatment of the esophageal cancer.

The thoracoscopic esophagectomy was initially performed in the left lateral decubitus similar to the classic technique, because in the event of some hemorrhagic incidents it was necessary to convert the case, performing the emergency thoracotomy is much easier.

Cuschieri *et al.* have improved the technique by changing the position from the left lateral decubitus to the procubitus which allowed the operation without a complete collapse of the lung aiming at the reducing of the postoperative lung complications that are the most rewarding (6).

Palanivelu *et al.* published a series of 130 patients who benefited from thoracoscopic esophagectomy with the patient in the prone position using a right posterior approach to which in addition to ventilation of the left lung, it was possible to partially ventilate the right lung. The average duration of the procedure was 220 minutes (160-450 minutes). The average hospitalization in the ATI section was 1 day (1-32 days). Pneumonia was one of the postoperative complications to 1.54% of patients (7).

The thoracoscopic esophagectomy performed in a left semi-prone position combines the advantages of the left lateral decubitus (allowing a rapid conversion) and prone position (which offers a more accurate view of the operating field and facilitates a complete mediastinal lymphadenectomy (fig. 2). In addition to mobilization of the conduit, celiac lymphadenectomy, pyloroplasty and jejunostomy performed using a laparoscopic approach represent the minimally invasive alternative for the radical treatment of esophageal cancer.

The first robotic esophagectomy was performed through transhiatal laparoscopic approach by Horgan S. in 2003 (8).

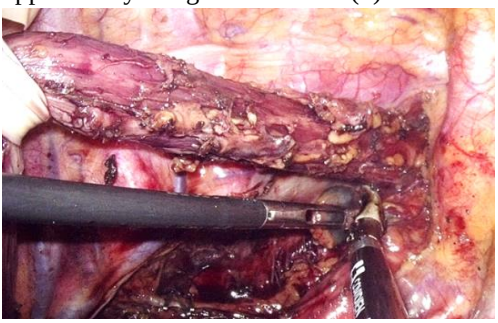

Fig. 2. Mediastinal lymphadenectomy

Some limitations of the standard minimally invasive esophagectomy which include bidimensional view, low grade of free mobility, narrow operating field of mediastinum and low coordination between eyes and surgeon's hand, have been eliminated by robotic surgery (fig. 3). Robotic platform reduces the complexity of thoracoscopic and laparoscopic maneuvers using the technology of endo-wrist da Vinci™ robotic upper arm (instrumental joint has 7 grades of mobility (9).

3D image of the highest augmented HD resolution, the ability of performing fine movements and filtering the tremor of the surgeon's hand are other advantages of robotic approach during esophageal dissection, allowing to perform an extended mediastinal lymphadenectomy and a "hand-made" esophago-gastric anastomosis (10).

Another unexpected advantage of robotic surgery is represented by the reducing of learning curve (20 procedures would be enough) in comparison to the standard MIE, so it could increase the number of specialists who could achieve adequate and specific

competences in a much shorter period. (11). In this way, Ivor-Lewis robotic assisted esophagectomy (RILE) has replaced the modified McKeown triple approach (RELA) many times through performing a qualitative intrathoracic anastomosis (12-14).

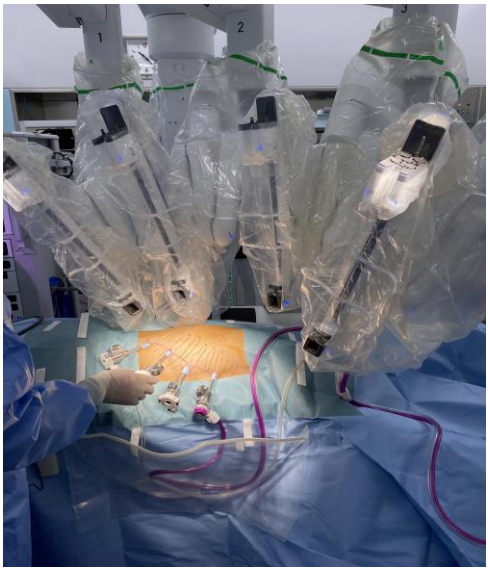

Fig. 3. Robotic esophagectomy

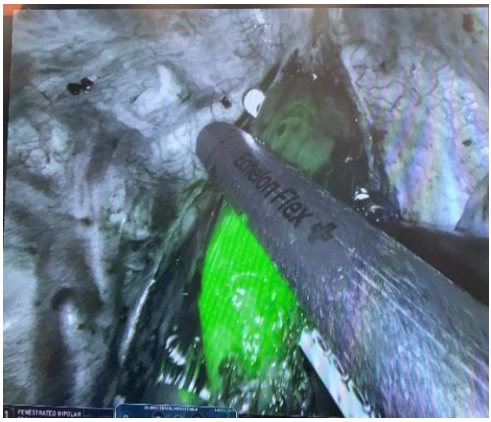

Fig. 4. ICG-enhanced robotic assisted surgery - DaVinci Firefly

The robotic platform has one or two DaVinci master units with a 3D HD camera system and near infrared imaging (fig. 4). The use of two consoles allows first assistant to perform surgical maneuvers and this assembly is useful for training.

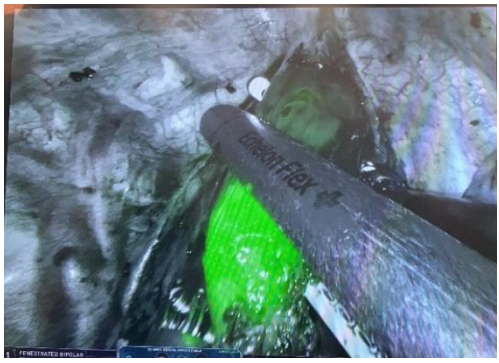

Fig. 4. ICG-enhanced robotic assisted surgery- DaVinci Firefly

Esophagectomy is associated with mortality, significant comorbidities and a long-term recovery and the results are based on the experience of surgical centers where the operation is performed, the surgeon and his team, and on involvement of an intensive care unit team which is ready for the treatment of non-surgical immediate or distant postoperative complications. MIE has the advantages of representing a less traumatic procedure with a short postoperative recovery and less pulmonary complications or infections of postoperative wounds.

Minimally invasive esophagectomy has long learning curve, but the expertise in open esophageal surgery is difficult to gain, and the knowledge about advanced techniques of minimally invasive surgery is mandatory. Technical difficulties in case of an esophageal tumor are similar to open surgery, thus, the enlarged image in the operating field could be an advantage for minimally invasive esophagectomy.

MIE enables the simplification of postoperative medical care (blood transfusions, postoperative treatment that relieves the pain), the decrease of the incidence for post-

operative complications, especially pulmonary complications and postoperative infections, deep veins thrombosis, shorter hospitalization and rapid social reinsertion.

The distant oncological results of minimally invasive esophagectomy analyzed in randomized clinical trials (TIME, MIRO and ROBOT) were recently published. Thus, patient survival at 3 years was 42.9% MIE vs 41.2% EC in the TIME trial, 67% MIE vs 55% EC in the MIRO trial, and overall survival at 5 years was 42% in the ROBOT study (15-17). The results of randomized clinical trials thus confirm the fact that minimally invasive esophagectomy reduces postoperative complications in resectable esophageal cancer with oncological results similar to open esophagectomy.

Summing up the expertise in open esophageal surgery and laparoscopic surgery of gastro-esophageal junction in the General and Esophageal Surgery Department, Sf. Maria Clinical Hospital, Bucharest, the minimally invasive esophagectomy has been performed using the modified 3-stage McKeown approach since 2015(the operative technique is described in *"Tratat de Patologie și Chirurgie Esofagiană"* edited by the Romanian Academy Publishing House in 2017 (fig. 5) and *"Surgery of the Esophagus"*, revised and added edition and translated into English published by the Romanian Academy Publishing House in 2019 (fig. 6) .

The 3-stage approach is performed in our Clinique because it does not imply performing an intrathoracic anastomosis which, in the occurrence of a mediastinal fistula, could lead to mediastinitis with significant postoperative morbidity and mortality. A cervical leak could benefit from conservative treatment, and an anastomotic stenosis is optimally resolved by performing endoscopic dilations (18).

Technological advances in esophageal surgery

Recent technological advances of minimally invasive surgery focusing especially on the areas of **imaging, instrumentation, cameras and robotics**.

The augmented **3D High-Definition image, 4K Ultra HD** or **8K camera**, provides an excellent visual field, that allows accurate identification of dissection planes and extensive periesophageal and perigastric lymphadenectomy. Near-Infrared Fluorescence is available in multiple endoscopic platforms including the DaVinci Robot Firefly system. NIF allows intraoperative tumor localization and in the assessment of gastric conduit perfusion, but also in mediastinal lymphadenectomy. Single-port Video Assisted Surgery has proven its usefulness both in the abdominal approach and in the thoracic approach, being also available with the DaVinci robotic system. Tri-Staple™ Technology offers a safer anastomosis and is an essential element in esophageal surgery. Mini-thoracoscopy has not yet entered esophageal surgery, but it finds a very good use in pediatric surgery.

The EndoEye Flex 3D deflectable videoscope finds a very good use in the recently promoted and increasingly used approach, namely mediastinoscopically assisted transhiatal minimally invasive esophagectomy.

Intraoperative recurrent laryngeal nerve monitoring reduces the risk of recurrent nerve damage during a crucial time of esophagectomy, namely upper mediastinal lymphadenectomy (fig. 7).

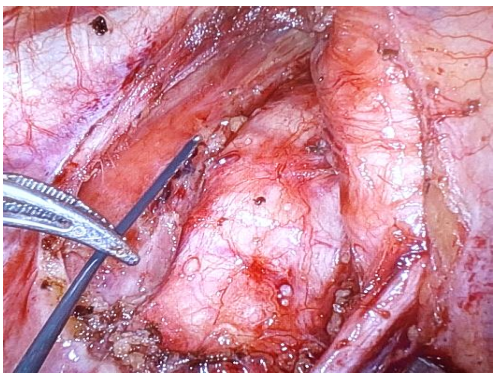

Fig. 7. Intraoperative recurrent laryngeal nerve monitoring

Surgical robotic systems will take off in the coming years with the expiration of the patents of the first DaVinci surgical robot. The first modular robotic systems have already appeared (Hugo from Medtronic, Versius (CMR Surgical Ltd. UK, the last one also available in the "Sf. Maria" Clinical Hospital Bucharest) which offer increased mobility of the robotic arms and reduce the conflict between instruments which is essential in small rigid spaces such as the ribcage.

Artificial intelligence has also begun to make its presence felt, advanced software programs have already been included in endoscopic platforms and are used in the detection of esophageal cancer through real-time analysis during endoscopy. Other applications with clinical utility are sentinel node navigation surgery, AI for learning esophagectomy, real-time detection of the recurrent nerve, predicting postoperative complications, machine learning for reducing readmissions after esophagectomy or AI for predicting esophageal cancer recurrence.

In the future, the following artificial intelligence technologies will probably be available in esophageal surgery: Surgical Training in Virtual Reality (VR) with realistic surgical simulations, AI as the Surgical Mentor, Personalized 3D Patient Models: 3D replicas of patient anatomy, The Infallible Robotic Aide: AI-empowered surgical robots, Holographic Surgical Visualization: interactive holograms, real-time 3D view or Postoperative Care Revolution: personalized rehabilitation after esophagectomy.

Artificial Intelligence for esophageal cancer patients is already a support tested by patients with esophageal pathology and which offers detailed information about the diagnosis and treatment of various esophageal diseases. AI will require the evolution of work practices, but will also enhance

patient safety and surgical quality outcomes, and provide significant value for surgeons and health systems. The use of AI in surgery is still evolving, and its implementation should always be supervised and guided by qualified healthcare professionals. As surgeons, we must not forget that the development in surgery was based on technological advances.

Advanced technology and optics of endoscopic surgery will allow better assessment of anatomical plans, a very good access to narrow spaces, and therefore a more precise dissection with lower trauma in esophageal cancer surgery.

The long-term outcomes of surgical treatment of esophageal cancer are an additional motivation for treatment orientation in order to obtain good results in quality of life of the patients in the first postoperative year, results in which minimally invasive technique is surpassing open technique.

The modern Upper Gastro-intestinal surgeon should offer to the patients the opportunity of benefit of the minimally invasive approach and he should perform an esophagectomy with low morbidity and mortality.

Evaluating the results of minimally invasive treatment of esophageal cancer is a constant concern worldwide, given that in some countries minimally invasive esophagectomy has become the standard indication, and open esophagectomy is performed only for the treatment of complex cases.

A RETROSPECTIVE INVESTIGATION ON THE INCIDENCE, CLINICAL CHARACTERISTICS, AND OUTCOMES OF PNEUMOTHORAX IN HOSPITALIZED COVID-19 PATIENTS IN NORTH-EAST OF ROMANIA (Abstract): The COVID-19 clinic ranges from asymptomatic to critical and fatal disease. Pneumothorax and pneumomediastinum are rare complications of COVID-19 infection but can occur at any time during the disease. The **aim** of this retrospective study was to analyze the impact of acute respiratory complications on patients diagnosed with SARS-CoV-2 infection. **Materials and methods:** 177 patients with COVID-19 were recruited to analyze the correlation between pneumothorax and demographics and general data of the patients. **Results:** In our study, pneumothorax or pneumomediastinum was much more frequent among younger, smoking individuals from urban environments. Moreover, the pneumothorax group had statistically significantly higher white blood cells and erythrocyte sedimentation rate values than the control group. The duration of hospitalization in patients who developed pneumothorax was similar to those who did not develop this complication. **Conclusions:** Patients experiencing this consequence had a significantly higher mortality rate compared to those in control groups. Although the precise origins of this complication remain unclear, individuals with preexisting pulmonary dysfunction appear to experience it more frequently. **Keywords:** COVID-19, COMPLICATION, PNEUMOTHORAX, PNEUMO-MEDIASTINUM, RETROSPECTIVE STUDY.

INTRODUCTION

In March 2020, the World Health Organization declared the COVID-19 pandemic. The Coronavirus disease 2019 (COVID-19) cause serious damage to the respiratory system. As a result of this damage air can pass into the intrapleural space or into the mediastinum and pneumothorax or pneumomediastinum can develop. Barotrauma, which includes pneumothorax or pneumomediastinum has been observed as an emerging complication in CODIV -19 patients (1, 2, 3). COVID-19 may cause spontaneous pneumothorax to the many progressive pathological changes in the lungs such as pneumonia, cystic changes or enlargement of blebs. Also, in clinically observed COVID-19 cases pneumothorax can develop without clinical or radiological parenchymal changes in the lung (4). Traumatic pneumo-

thorax results from injury to the pleura, as well iatrogenic pneumothorax result from injury to the pleura during medical procedures. Secondary spontaneous pneumothorax is a pneumothorax that occurs as a complications of underlying lung disease and the primary spontaneous pneumothorax is defined as pneumothorax in a healthy individual. Spontaneous pneumothorax and pneumomediastinum have been described as complications of COVID-19 with a wide incidence from 10% in patients with COVID-19-related acute respiratory distress syndrome, increasing to 24% in patients receiving mechanical ventilation (5). In another study by Geraci et al., the incidence of pneumothorax in COVID-19 was reported as 7.4% (6). Patients experiencing this consequence had a significantly higher mortality rate compared to those in control groups (7). Although the precise origins of this complication remain unclear, individuals with preexisting pulmonary dysfunction appear to experience it more frequently (7). In our study, we aimed to describe the clinical characteristics and outcomes of patients with pneumothorax or pneumomediastinum or both due to COVID-19 pneumonia.

MATERIALS AND METHODS

Study design. Patients were recruited for this retrospective study from the "Sfântul Ioan cel Nou" County Emergency Hospital from Suceava, designated for treating SARS-CoV-2 infections. The study included patients diagnosed with SARS-CoV-2 infection through PCR (polymerase chain reaction) testing from March 2020 to November 2020.

Ethical Approval. The study received approval from the Ethics Committee of the "Sfântul Ioan cel Nou" County Emergency Hospital from Suceava (No. 4/ 27.11.2020).

Patients. In the study interval, out of 28,678 admitted patients, 7,325 were confirmed with a diagnosis of Covid-19. Initially, the study included 113 patients confirmed with Covid-19 infection, pneumothorax, and/or pneumomediastinum. After excluding 7 patients with traumatic pneumothorax and 6 patients with iatrogenic pneumothorax, the study included 100 patients. The diagnosis of pneumothorax or pneumomediastinum was based on clinical symptomatology and confirmed by imaging. In the control group, we included only 77 patients out of 7212 who had a confirmed diagnosis of SARS-CoV-2 infection but no diagnosis of pneumothorax or pneumomediastinum. In the selection of patients for the control group several criteria of similarity were rigorously followed, such as hospital admission in the same period, data regarding the onset of COVID-19 disease, similar symptoms and demographic data such as environment of origin or smoking status. These patients also presented respiratory pathology in association such as chronic obstructive pulmonary disease, bronchiectasis, bronchial asthma or post-tuberculosis lung sequelae, so definite diagnosis of pre-existing lung damage. The inclusion criteria were age over 18 years, a diagnosis of SARS-CoV-2 infection, and pneumothorax. The exclusion criteria were age under 18, pregnant individuals, and the negation of a Covid-19 diagnosis.

Statistical analysis. The data analysis was realized using *SPSS version 23.0* (Statistical Package for the Social Sciences, Chicago, Illinois). For continuous variables, the data were presented as median with interquartile range or as mean ± standard deviation (SD). For categorical variables, the data were presented as the

number of cases with percent frequency. Continuous normally distributed variables were compared by Independent Samples t-Test in case of two samples, or by One-Way ANOVA, in case of comparisons of more than two samples. Categorical comparisons were performed by Fisher's exact test or by Chi-square test.

RESULTS

Thus, we have enrolled in our study 177 patients (100 in the pneumothorax / pneumo-mediastinum group and 77 in the control group). Regarding the general characteristics of the two populations, we have observed that the patients included were predominantly males from urban area. There were no significantly statistical differences regarding the age of the two groups. Regarding the educational status, we can observe that most of the included individuals had a medium level of education, followed by the ones with high education.

Regarding the employee status, again no statistically significant differences could be observed, but it worth mentioning that the majority of them were retired, followed by full-time workers. Moreover, we can observe that in the pneumothorax group there was a higher prevalence of smoking and a lower BMI, compared to the control group (tab. I).

TABLE I.

General characteristics of the study groups

General characteristics		Pneumothorax Group (n = 100)	Control Group (n = 77)	p
Gender n (%)				
	Male	56 (56.0%)	49 (63.6%)	0.355
	Female	44 (44.0%)	28 (36.4%)	
Living environment, n (%)				
	Rural	41 (41.0%)	25 (32.5%)	0.275
	Urban	59 (59.0%)	52 (67.5%)	
Age, years (mean ± DS)		59.98±13.95	64.11± 15. 18	0.066
Education status, n (%)				
	No education	10 (10.0%)	2 (2.6%)	0.070
	Medium level of education	40 (40.0%)	51 (66.2%)	0.001
	High level of education	32 (32.0%)	23 (29.9%)	0.870
	Unspecified	18 (18.0%)	1 (1.3%)	0.000
Employee status, n (%)				
	Household	8 (8.0%)	3 (3.9%)	0.353
	Full-time	43 (43%)	28 (36.4%)	0.440
	Retired	49 (49%)	46 (59.7%)	0.173
Alcohol consumption, n (%)		4 (4.0%)	1 (1.3%)	0.389
Smoking, n (%)		41 (41.0%)	23 (29.9%)	0.083
BMI (kg/m^2)		25.06 (22.40; 32.00)	27.98 ±5.14	0.157
Days of hospitalization (mean± SD)		14.00 (8.75; 18.25)	13.37±7.05	0.070

The prevalence of COVID-19 infection types within the pneumothorax group, where the moderate form exhibited the highest prevalence, succeeded by the severe form, and the mild type was the least frequent. In contrast, the control group showed the highest prevalence in the severe form, followed by the moderate and mild types (tab. II).

TABLE II.
Types of the COVID-19 infection within the study groups

Type of disease	Pneumothorax Group (n = 100)	Control Group (n = 77)	p
Mild	19	13	0.844
Moderate	42	30	0.758
Severe	39	34	0.539

When evaluating the symptomatology of the patients, we observed statistically significant differences regarding nausea, ageusia, anosmia, myalgia, and asthenia, these symptoms being more frequent in the pneumothorax group compared to the control group. Regarding the cough, we can observe that the dry one was more prevalent in the pneumothorax group compared to the control group. Statistical significance was also observed for almost all the classes of dyspnea (tab. III).

TABLE III.
Associated symptomatology in the two studied groups

Symptomatology		Pneumothorax Group (n = 100)	Control Group (n = 77)	p
Nausea		26 (26.0%)	7 (9.1%)	0.006
Vomiting		4 (4.0%)	5 (6.5%)	0.505
Ageusia		24 (24.0%)	3 (3.9%)	0.000
Anosmia		25 (25.0%)	6 (7.8%)	0.003
Myalgia		63 (63.0%)	24 (31.2%)	0.000
Headache		60 (60.0%)	16 (20.8%)	0.000
Asthenia		87 (87.0%)	42 (54.5%)	0.000
Thoracic pain		46 (46.0%)	30 (39.0)	0.363
Cough	Dry	64 (64.0%)	37 (48.1%)	0.401
	Productive	10 (10.0%)	17 (22.1%)	0.042
Dyspnea	MRC 0	17 (17.0%)	25 (32.5%)	0.021
	MRC 1	29 (29.0%)	9 (11.7%)	0.006
	MRC 2	25 (25.0%)	18 (23.4%)	0.861
	MRC 3	21 (21.0%)	8 (10.4%)	0.067
	MRC 4	8 (8.0%)	17 (22.1%)	0.009

We can observe that in the pneumothorax group there are statistically significant higher values of the while blood cells and erythrocyte sedimentation rate compared

to the control group. Moreover, it worth mentioning that the number of platelets, urea and creatinine were higher in the pneumothorax group compared to the control, but without statistical significance (tab. IV).

TABLE IV.

Laboratory tests in the two studied groups

Laboratory values	Pneumothorax Group (n = 100)	Control Group (n = 77)	p
WBC	10.52 ± 4.12×10^3/mm^3	7.77 ± 3.62 ×10^3/mm^3	0.000
PLT	256.66 ± 96.38	219.00 (161.50; 309.00)	0.318
ESR	99.50 (78.00; 124.00)	59.81 ± 39.35	0.000
CRP	11.64 (3.31; 24.15)	20.18 (6.64; 45.56)	0.422
Urea (mg/ dL)	45.00 (34.00; 62.75)	38.00 (29.30; 62.55)	0.606
Creatinine (mg/ dL)	0.90 (0.74; 1.24)	0.89 (0.68; 1.20)	0.101
GFR (ml/min/1.73 m^2)	78.86± 33.65	84.05 ± 28.14	0.315

WBC – white blood cells, PLT – platelets, ESR – erythrocyte sedimentation rate, CRP – C reactive protein, GFR – glomerular filtration rate

DISCUSSION

The study aimed to quantify the number of patients who developed pneumothorax following SARS-CoV-2 infection and identify the risk factors that caused the development of sars-cov-2. In our study, the incidence of SARS-CoV-2 infection was 25.46% among patients hospitalized at the "Sfântul Ioan cel Nou" County Emergency Hospital Suceava, from March 2020 to February 2021. In addition, the incidence of pneumothorax in patients with COVID-19 was 1.36%. Studies reveal that patients with this infection encounter pneumothorax much more frequently than those with other respiratory infections, with an incidence of 10% among those with severe forms of the disease (2). In the cases included in the study, the incidence of pneumothorax was approximately the same for both moderate (42%) and severe (39%) forms of the disease, but without significant statistical significance. On the other hand, data from the literature show strong correlations between the severe form of the disease and the occurrence of complications such as pneumothorax (9).

Moreover, a systematic review published in 2020, which included 9 observational studies, highlights that the rate of pneumothorax would be higher among men (10, 11, 12). This can also be observed among the patients included in our study (56% *vs.* 44%). One possible cause for this difference between sexes is that smoking is more common among men. Regarding the symptoms, patients most frequently presented to the hospital with dyspnea (83%), myalgia (63%), headache (60%), asthenia (87%), anterior chest pain (46%), and dry cough (64%).

Smoking is a well-known risk factor for respiratory diseases. The patients included in the study with pneumothorax had a much higher smoking rate than the control group (41% vs. 29.9%). Still, there was no statistically significant correlation between smoking and this complication arising from SARS-CoV-2 infection. Even though smoking is considered an emerging risk

factor for pulmonary pathologies such as chronic obstructive pulmonary disease, studies in the literature have failed to identify a correlation between this habit and the occurrence of pneumothorax in patients with COVID-19 (12, 13).

The urban environment is another risk factor involved in the development of pneumothorax in COVID-19 patients. It seems that existing pollution, lifestyle, sedentary behavior, and diet-factors predominant in cities-negatively influence the progression of COVID-19. From a future perspective, this idea should be further explored to see if the number of pneumothorax cases is higher in industrialized cities compared to smaller towns (14).

Increased white blood cell counts and inflammatory markers like CRP and ESR indicate an inflammatory status, which prolongs the healing period of lung infections and increases the risk of complications (15). In the case of patients monitored at the "Sfântul Ioan cel Nou" County Emergency Hospital Suceava, it is observed that both white blood cells and ESR have a much higher value among patients with pneumothorax, while the CRP value is lower in these patients.

Throughout the pandemic, several studies have emerged highlighting that obese patients were much more prone to complications associated with SARS-CoV-2 infection than normal-weight patients. Abdominal adipose tissue predominantly hinders respiratory movements, leading to greater respiratory effort. Furthermore, obesity is considered a factor that maintains the inflammatory status, promoting the occurrence of numerous complications (16). However, our study did not find a statistically significant correlation between BMI and the occurrence of pneumothorax.

Another particularity of our study would be the duration of hospitalization, although pneumothorax typically results in a higher number of hospitalization days, the two groups showed no statistically significant differences (10).

CONCLUSIONS

Since 2020, infection with the SARS-CoV-2 virus has caused numerous deaths due to associated complications. One of the most severe complications encountered in these patients was pneumothorax, which led to an increased length of hospitalization and, consequently, to exposure to the risk of developing superadded respiratory infections or even those associated with medical procedures. In our study, it seems that this complication was much more frequent among younger, smoking individuals from urban environments.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding.

MINIMALLY INVASIVE APPROACH IN SURGERY OF INGUINAL HERNIA

The history of groin hernia repair dates back to the times of Ancient Egypt and Greece, including also Hippocrates reference, Galen anatomical insights and passing to Middle Ages in 13th Century when Ronaldo Parmensis in *Practica Chirurgiae* established a cornerstone with details of medical treatment of hernia with an astonishing picture.

Many other surgeons contributed to the development of groin hernia repair and split it into two major directions, both of which rely on the anatomical concept of the myopectineal orifice and the pathological concept of repairing the fasciascie transversalis (Bassani, Shouldice, 1953).

One direction is autologous repair, using the patient's own tissue without implanting foreign materials, with the advantages of no risk of immunological reaction to foreign bodies, lower cost as no mesh is required, but with important disadvantages of using weak patient tissue for repairing a weak parietal structure (like "poor tailoring patches"), more postoperative pain (2) but, mainly, not respecting the "tension free" concept introduced by Lichtenstein in 1986.

The other direction is heterologous repair started with Stoppa in 1975, using a foreign material to consolidate the weak inguinal region and with the advantages of respecting the tension-free concept with the consequences of less pain and recurrences, but with disadvantages of possible immunological and inflammatory reactions to foreign bodies, mesh infection, and higher costs because of the mesh requirement (3).

Currently, autologous techniques are used with good results in a few places, such as the Shouldice Center, hernias with contaminated tissues, or mesh contraindications.

Heterologous techniques are now the gold standard for most parietal defects made in an open approach, such as the *Lichtenstein procedure*, and in minimally invasive approach, like the transabdominal preperitoneal technique (TAPP) and total extraperitoneal technique (TEP) - intraoperative aspects of TEP repair. In the EHS guidelines, mesh-based techniques-particularly the *Lichtenstein technique* - and endoscopic methods are recommended for treatment of symptomatic primary inguinal hernia in adult men (strength of recommendation IA) (4). Robotic surgery as a minimally invasive approach has shown good results.

The competition in inguinal hernia repair lies between the *Lichtenstein procedure* and *minimally invasive surgery* (MIS). The *Lichtenstein procedure* is well standardized, has a shorter operative time, is less expensive, and requires local or regional anesthesia. MIS brings the benefits of laparoscopic procedures: short hospitalization, reduced return to work time, and fast recovery.

The answer to the question of which is the best approach in hernia repair was determined by a prospective randomized study in 2022 on 174 patients comparing the surgical outcomes of TEP and *Lichtenstein tension-free open mesh inguinal hernia repair* (5). The surgical outcomes evaluated were postoperative pain, recurrence rate, operative time, and complications including seroma, infection, and chronic groin pain.

In conclusion, although TEP provides evidence of a longer operative time and learning curve, advantages such as less

postoperative pain, early resumption of normal activities, less chronic groin pain, and comparable recurrence rate with *Lichtenstein repair* are significant. Therefore, TEP can be performed by experienced surgeons with acceptable outcomes and fewer postoperative complications. The indications for MIS are unilateral, bilateral, and incarcerated inguinal hernia (4). In experienced hands, even large and strangulated inguinal hernias can be considered, depending on the patient particularities and anesthesia tolerance. TAPP has the advantage of easy reduction of the hernia sac and treatment of its contents (epiploon resection, enterectomy with anastomosis, etc.). TEP is also possible, but it requires first, intraperitoneal entry for reduction and content treatment and then, followed by withdrawal of the camera in the proper space to continue the procedure. Between TAPP and TEP, we consider that TEP allows the use of a larger mesh and avoids the boring and time-consuming step of peritoneal suture, with a lower risk of peritoneal adherence, but we admit that our most experience is with TEP. Currently, glue is used instead of the peritoneal sutures. Another advantage of TEP is that it does not require mesh fixation to the Cooper's ligament.

Regarding mesh fixation, a systematic review and meta-analysis of randomized controlled trials included eight trials with 2,617 patients with 2,878 hernias (6). The non-fixation group was associated with lower postoperative pain scores at 24 hours and 6 months, shorter mean operative time, and lower incidence of urinary retention. There were no significant differences in the recurrence rates of patients with an inguinal orifice smaller than 4 cm.

Another point of interest is the necessity of controlling the exploration and repair of an eventually occult inguinal hernia. A systematic review of 13 studies (one randomized and 12 observational cohorts with 5,000 patients) concluded that immediate repair of occult contralateral inguinal hernias diagnosed at the time of elective hernia repair is not justified, and following intraoperative diagnosis of an occult contralateral hernia, more than 70% of the patients will not require treatment, without contralateral exploration less than 10%, are likely to present for contralateral repair. Immediate diagnosis and repair can result in more complications than expectant management (7).

What about the defect closure? We believe that a defect more than two centimeters should be laparoscopically closed, preferably with a V-loc suture to reduce seroma formation, or loop closure (8).

Regarding the learning curve there is data showing that TEP and TAP seems to be similarly, with 20-60 cases for a beginner in TEP and 20-65 for TAPP, as couple of studies present (9, 10).

There are some limitations of the minimally invasive approach in inguinal hernia: intolerance to pneumoperitoneum with necessity of conversion, reduced space of dissection, adherences, and poor knowledge of proper anatomy, mostly in TEP.

Another difference is the necessity of adequate instrumentation to enter the peritoneal space during TEP. With more experience, proper space entry could be done with the usual laparoscopic instrumentary.

Finally, I consider that each patient should have a personalized indication for TAPP, TEP, or an open approach, *Lichtenstein procedure*. TAPP and TEP in robotic surgery have more facilities but with higher costs (11).

NAVIGATING GENDER DYSPHORIA THROUGH POLITICAL TURMOIL: A ROMANIAN PERSPECTIVE (Abstract): In the charged environment of the 2024 national and international legislative elections, this study explores how campaign rhetoric and media narratives reshaped Romanian adults' attitudes toward gender dysphoria, incongruence and minority identities. Its **aim** is to determine the extent to which evolving legislative debates influence public perceptions and individuals' self-assessed social acceptance of gender diversity. We compared acceptance levels before and during the elections, identified demographic and psychosocial factors driving respondent engagement and assessed the prevalence of perceived discrimination and institutional obstacles of adults with diverse gender identities. This study shows how political rhetoric, media and public attitudes either promote or impede gender inclusivity in Romania. **Materials and methods:** We conducted a comparative, exploratory, descriptive cross-sectional study before and during the 2024 elections among Romanian adults aged 18-65 y.o. **Results**: This study reveals that Romania's 2024 legislative election cycle, marked by polarized campaign rhetoric and intensified media narratives, coincided with a measurable decline in self-assessed social acceptance of gender diversity and a surge in perceived discrimination. Demographically, young, urban and highly educated women led participation, yet cisnormative attitudes continued to dominate across all groups. Although legislative frameworks remained largely neutral, aggressive political discourse and social media messaging amplified psychological distress, discouraged open dialogue about gender dysphoria and deterred engagement in research participation. **Conclusions:** These findings reveal that political and media climates shape public views of diverse identity and gender dysphoria, calling for education, policy, and community initiatives to foster inclusion. **Keywords:** IDENTITY, GENDER, DYSPHORIA, CISNORMATIVE, INCLUSIVITY.

INTRODUCTION

Gender dysphoria, as defined by DSM-V, is a significant incongruence between a person's experienced gender and their assigned gender at birth, lasting at least six months. Introduced in 2013, it shifted focus to incongruence itself, emphasizing distress as the key diagnostic criterion (1).

ICD-11 similarly includes "gender incongruence" to ensure healthcare access but classifies it under sexual health instead of mental disorders, using terms like "expe-

rienced gender" and "assigned sex" instead of "opposite sex" or "anatomical sex". While both DSM-V and ICD-11 highlight distress and dysfunction as diagnostic criteria, ICD-11 does not mandate these aspects for diagnosis (2).

The historical evolution of gender identity has transitioned from psychiatric diagnosis to depathologization, highlighting a distinctive feature of contemporary times and the focus of this study (3, 4). While references to gender change appear in Greco-Roman sources, individuals considered transgender today existed in premodern eras. By the mid-19th century, medical interest in this phenomenon emerged, and depathologization currently shapes official attitudes. Though the etiology of transgender behavior remains unclear, research suggests neurobiological underpinnings, dismissing the idea that it stems from social trends or should be subject to religious or political regulation.

Gender dysphoria frequently prompts discussions on the socio-cultural and political conditioning of its public recognition, tied to societal acceptance. Another perspective views these elements within gender ideology as a phenomenon of "social contagion", which is notably widespread in Western societies (3, 4, 5).

This research takes place during a tumultuous historical period marked by significant global changes that also resonate within Romanian society. Some authors highlight ideological clashes impacting traditionalist cultures, driven by themes like human-induced climate change and gender ideology, which have become prominent in political campaigns. In 2024, approximately 1.6 billion people worldwide elected new political leaders, reflecting ongoing ideological shifts between "globalism" and "sovereignism", reshaping citizens' lives. These societal tensions often foster intolerance and discrimination, including against nonconforming gender identities, regardless of whether individuals experience gender dysphoria.

The study analyzes data from specialized literature on changes in the "social acceptance" of gender nonconformity and dysphoria within the politically charged context of the 2024 legislative elections across various countries. International developments are seen as influencing Romanian society. In the U.S., gender diversity was historically promoted as an expression of personal authenticity, aligning inner experiences with self-perceived gender and sexuality. Gender was viewed as self-constructed, sexuality as fluid, and monogamy as a "cultural constraint".

Progressive policies in the U.S. and Canada have enabled gender self-identification from an early age and medical transition without requiring gender dysphoria, though phenomena like "rapid onset gender dysphoria" remain debated. Social media plays a significant role in influencing gender incongruence among youth, with global attitudes shifting from intolerance to greater acceptance. Studies document widespread "gender affirming" procedures, often undertaken without dysphoria as a criterion (6, 7, 8, 9, 10).

Acceptance of gender diversity is closely tied to political context. Liberal policies foster inclusivity, while conservative ideologies often correlate with trans prejudice. Recently, social acceptance in the U.S. and Western Europe has stagnated, partly due to negative political discourse, especially from right-wing parties. This shift affects healthcare, education, and overall societal attitudes, as seen in studies like D. Brokke's on LGBT+ acceptance in the Netherlands (11, 12).

Reports such as GLAAD's "Accelerating Acceptance Study" show that while

overall acceptance of LGBTQ individuals remains high, support has declined. In 2024, 80% of respondents supported equal rights for LGBTQ individuals, down from 84% a year prior. Additionally, 70% of Gen Z LGBTQ adults reported discrimination based on their sexual orientation (12, 13).

The influence of politics on social acceptance is evident in legislative decisions. The "2024 in LGBT Rights" report highlights 78 legislative changes globally in 2024 impacting LGBT individuals, with 123 changes in 2023 and 625 since 2020 (13). These changes affect civil rights, specialized healthcare for transition processes, legal document updates, and the transitioning of minors. While approaches vary, the scope of the "trans" phenomenon is widely recognized, especially in Western countries, where many aspects are legally regulated (13).

In 2024, gender-related rights varied significantly worldwide: In Canada, "Gender Affirming Care" was legal, with specific regulations differing by region, but funding was limited to individuals with gender dysphoria. It was also legal in Wales, UK, but banned in Iraq. Blood donation bans for LGBTQ+ individuals were lifted in Honduras, Denmark, Czechia, Bermuda, Estonia, and the Netherlands. Germany recognized nonbinary genders and allowed annual gender and name changes based on self-identification under the "Selbstbestimmungsgesetz". In the USA, "Gender Affirming Care" and gender transitions were restricted in states like Georgia, Kentucky and Idaho, while other states like Arizona and Florida permitted such rights, although shifts in policies reflected political changes. Tennessee enacted laws against LGBTQ+ couples and transgender individuals. Peru classified transgenderism as a mental disorder. Same-sex marriage became legal in Aruba, Curaçao, Greece and Estonia, while civil unions were recognized in Lithuania. Nepal legalized same-sex unions without granting full civil rights. Anti-LGBTQ propaganda laws were enacted in Bulgaria, South Carolina, El Salvador and Transnistria, the latter imposing imprisonment to "protect traditional values". Conversion therapy bans were introduced in Mexico, parts of Switzerland, Peru and Portugal. Namibia and the Dominican Republic decriminalized homosexuality, while Iraq maintained criminalization but allowed gender-confirmation surgeries for intersex children.

In Romania, a traditionally conservative society, gender nonconformity has gained visibility but faced resistance. While there is no specific legislation, a 2023 European Court of Human Rights ruling required Romania to recognize and protect LGBTQ families (14). Adherence to EU directives led to the acknowledgment of same-sex marriages performed in EU countries, though public acceptance remains low, with over 60% opposing LGBTQ rights according to surveys (15). Nevertheless, societal tolerance has grown incrementally, with nearly 40% expressing support or neutrality toward the LGBT community.

Efforts promoting diversity and inclusivity reflect global legislative shifts, but significant disparities remain across regions (15, 16).

Professor Daniel David highlights that Romanian psychology tends to resist change, favoring stability and continuity. He notes that Romania scores high in uncertainty avoidance (17), perceiving future changes as threats rather than development opportunities. In this context, gender nonconformity and dysphoria pose significant challenges for social acceptance.

Following major political shifts in the U.S. in January 2025, progressive gender ideology has been actively opposed by the

new administration. This shockwave is expected to influence Europe, including Romania, where transgender-related policies and healthcare interventions have not been widely implemented. In Western countries, many individuals who underwent gender transition procedures now face medical challenges, particularly in the U.S., where funding for specific healthcare has been halted. Similarly, progressive policies in Europe have faced increasing opposition, with legislative elections in 2024 bringing politically contrasting forces to power. Researchers have observed a decline in social acceptance of transgender individuals, a trend expected to continue into 2025 across Europe.

Future studies will shed light on how Romanian society, with its dominant cultural traditions, will adapt to and reposition itself regarding gender incongruence.

MATERIALS AND METHODS

This study examines the self-assessed social acceptability of gender incongruence and dysphoria among Romanian adults in 2024, amid limited awareness and heightened negative propaganda during electoral campaigns. While Romanian psychological traits suggest both tolerance and conservatism, public understanding of gender dysphoria remains low, often shaped by biased social media content. Political rhetoric in 2024 amplified intolerance, reflecting global tensions between progressive and conservative ideologies.

Using a comparative, exploratory and descriptive cross-sectional approach, the study distributed questionnaires twice monthly to Romanian adults (18-65 y.o.) via social media and messaging platforms. It analyzed social media posts, demographic data, and self-perceived discrimination during electoral campaigns. Data were collected across two periods: before (June 1st-July 1st, 2024) and during the elections (October 25th-November 24th, 2024) and correlated with in-depth interviews.

Findings indicate that aggressive political discourse negatively impacted social acceptance of gender identity. Challenges of the research included platform restrictions, misinterpretations and hostile responses. The study underscores the need for interdisciplinary collaboration, improved medical education and public health initiatives to enhance understanding and support for individuals with gender dysphoria.

Ethical guidelines ensured confidentiality and GDPR compliance, with data securely stored offline. The research adhered to European human rights standards, prioritizing human dignity. A total of 170 respondents participated, with significantly lower engagement during the campaign period, likely due to socio-political tensions.

RESULTS

The study highlights a noticeable decline in willingness to participate during the electoral period, potentially linked to heightened social tensions. Data collected included demographic details and responses to open-ended questions, complemented by in-depth interviews for a nuanced interpretation. The findings suggest a correlation between social tension and reduced engagement, emphasizing the impact of political propaganda on societal attitudes toward gender identity.

Young adults (18-29) showed the most interest, followed by those aged 30-39, with no participants over 60. Women were significantly more engaged, making up 85.88% of respondents. Gender identity was predominantly cisgender (81.1%), with

5.29% identifying as gender nonconforming and 2.94% choosing not to respond.

Most respondents lived in urban areas (79.41%) and had higher education (77.64%). Regarding marital status, 64.11% were in a relationship, with fewer married participants in phase II. Orthodox affiliation was 67.05%, lower than the national census (85%)

Professionally, 62.94% were unemployed (58.95% in phase I, 77.77% in phase II), with only 30.58% employed. Intellectual work was prevalent (51.49% in phase I, 33.33% in phase II, totaling 47.64%).

Most participants came from traditional family backgrounds. Some (13 total) reported parental preference for them to be the opposite sex, potentially influencing gender identity. Parental affection tied to gender was noted by 10 respondents.

A vulnerable psychological profile emerged, with 119 reported traumas. In phase I, serious illness of a loved one (36 cases), bullying (30), verbal abuse by fathers (20), family violence (19), and other parental abuse (neglect, withdrawal of affection) (18) were most common. In phase II, bullying (10), other parental abuse (7), family violence (5), and physical aggression by mothers (5) were frequently reported. Physical aggression by fathers was noted by 15 respondents across both phases.

Most participants did not seek psychiatric care (113 in phase I, 32 in phase II), while a small number did (19 in phase I, 4 in phase II). Two in phase I reported past psychiatric hospitalizations, and psychiatric treatment was mentioned by 14 respondents overall. Preference for alternative therapies was noted in 34 cases.

Self-harming behaviors were reported by 27 participants, with substance abuse including smoking (32 cases), alcohol (10 cases), and psychotropic medication use (7 cases). One respondent admitted to illegal drug use.

Eating disorders were confirmed by 12 respondents through specialist consultations. Suicide attempts, the most severe self-harming behavior, were acknowledged by 17 participants, with 4 declining to answer.

The DSM-V evaluation showed that most participants did not meet the criteria for gender dysphoria (90.29% in phase I, 86.11% in phase II). Among the 18 diagnosed, key issues included gender incongruence, distress and a desire for gender affirmation.

Of 170 respondents, only 7 considered medical affirming intervention, while 11 diagnosed individuals did not plan to transition. Four had already undergone gender affirmation procedures, one was in treatment, and three planned future interventions. A significant number (14 in each phase) declined to answer, reflecting reluctance to discuss sensitive topics.

Most respondents (91.76%) reported no legislative barriers to gender identity expression, while 3.52% faced obstacles, and 4.70% declined to answer. Workplace discrimination was noted by 3.52%, and 2.35% experienced healthcare discrimination, particularly among nonconforming individuals.

Overall, 8.23% perceived gender identity-based discrimination, with higher rates in phase II (16.66%) compared to phase I (5.97%), likely due to aggressive political discourse. Despite this, 88.23% did not perceive discrimination, reflecting Romania's traditionally tolerant traits, though phase II showed a decline in this perception.

Social media (47.05%) and television/mass media (26.47%) were key sources of gender identity information, with 73.52% acknowledging media influence. The study compared two periods: one

with low public interest and traditionalist views, and another during the electoral campaign, where gender identity was framed as a threat to family values and social morality.

Official data showed that 21.29% of Romania's 9.4 million presidential election voters supported conservative, traditionalist options, rejecting gender ideology. Among 711,067 diaspora voters, 55% favored sovereigntist views despite exposure to Western progressive ideologies.

In the parliamentary election, 30% backed conservative choices, with similar trends in urban and rural areas. Diaspora voters in the U.S. (69.64%), Australia (71.11%), Canada (75.60%), and Russia (58.59%) showed strong anti-progressive preferences, reflecting cultural resistance to gender ideology even abroad.

CONCLUSIONS

The socio-political climate in Romania mirrored the U.S. in 2024, where voters shifted toward conservatism, traditionalism, and intolerance of gender nonconformity, contrasting with the previous administration's progressive stance. Studies highlight the interplay between politics and religion, with Christian nationalism emerging as a key predictor of traditionalist gender ideologies, influencing broad support for the newly elected conservative U.S. president in 2024.

The study found that Romania's 2024 electoral campaigns negatively impacted participants' self-assessed social acceptance, regardless of gender identity, due to socio-political pressure. Participation declined during the campaign period, with most respondents being young, urban, highly educated women from traditional backgrounds. Cisgender identities dominated, with only 5.29% identifying as nonconforming and 2.94% opting not to disclose their gender identity, reflecting cultural conservatism.

Limited awareness of gender ideology was noted, with media-especially social media and television-shaping public perception. Psychological vulnerabilities, including parental divorce, bullying, and family violence, were common, with eating disorders and self-harm increasing in phase II. Psychiatric consultations were more frequent in phase I, while suicide attempts rose in phase II, possibly due to socio-political tensions.

Traditional cisgender identities remained dominant, with reported legislative barriers, workplace discrimination, and limited healthcare access. Social acceptance of gender diversity declined during the campaign, with fewer participants and increased reluctance to engage. The findings highlight the need for further research on societal attitudes and the influence of political and cultural factors on gender diversity in Romania.

The study highlights the impact of Romania's 2024 electoral campaigns on gender identity perceptions, with socio-political pressure reducing self-assessed social acceptance and participation. Traditional cisgender identities dominated, while nonconforming identities remained a minority, reflecting cultural conservatism.

Media, especially social media and television, shaped public perception. Psychological vulnerabilities, including trauma, bullying, and family violence, were common, with self-harming behaviors and eating disorders increasing during the campaign. Psychiatric consultations were more frequent in phase I, while suicide attempts rose in phase II, likely due to political tensions.

Despite some progress in tolerance, legislative barriers, workplace discrimination,

and limited healthcare access persist. The study underscores the need for further research, education, and policy development to foster gender inclusivity in Romania's evolving social landscape.

OUTCOMES OF ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION IN ACUTE MYELOID LEUKEMIA: A SINGLE-CENTER EXPERIENCE FROM THE IAȘI REGIONAL INSTITUTE OF ONCOLOGY (Abstract): Allogeneic stem cell transplantation (allo-SCT) remains the only curative treatment option for acute myeloid leukemia (AML) patients. We present the outcomes of 59 AML patients who underwent allo-SCT at our center. **Materials and methods**: We retrospectively analyzed patients transplanted between 2019 and 2024. Baseline characteristics included age, sex, ELN 2022 risk, disease status at transplant (CR1, CR2, active disease), donor type, GVHD prophylaxis. Outcomes evaluated were engraftment, acute and chronic GVHD, cumulative incidence of relapse (CIR), non-relapse mortality (NRM), overall survival (OS), disease-free survival (DFS). Survival was estimated by the Kaplan-Meier method. **Results**: The median age was 44 years. 84.7% of patients were transplanted in CR1. Donors included: matched sibling 42.4%, unrelated 49.2%, and haploidentical 8.5%. Incidence of grade II-IV acute GVHD was 16.9%, and chronic GVHD 25.4%. At a median follow-up of 26 months (95% CI: 32-44), OS and DFS were not reached. Patients transplanted in CR1 showed the best outcomes (mean OS 88.7 months; 2-year DFS: 74%), while CR2 patients had inferior results (mean OS 33.5 months; 2-year DFS: 40-45%). Differences were significant (OS p=0.004; DFS p=0.007). Measurable residual disease at day+90 was the single most robust factor for predicting outcome in both univariate and multivariable analysis. **Conclusions**: Our single-center experience confirms that allo-SCT is feasible and effective in AML, with outcomes comparable to international reports. The disease status at the moment of transplantation and measurable residual disease remain the most powerful prognostic factors to identify patients at high risk of relapse.

INTRODUCTION

Acute myeloid leukemia (AML) is a highly aggressive hematologic malignancy defined by the proliferation of immature myeloid precursors and extensive bone marrow (BM) infiltration, ultimately leading to patient demise in the absence of therapy. AML is a rare form of cancer, with an incidence of 5 cases per 100000 healthy individuals in Europe (1).

The last decade has seen significant advances in the therapy of AML, with the advent of the novel targeted molecular therapies or immunotherapies, used either in association with standard intensive "3+7" chemotherapy in younger patients or alongside hypomethylating agents in cases deemed unfit for an intensive approach. Despite these advances, virtually all patients are at risk of relapse. Relapsed AML has a dismal prognosis, with 2-year survival rates as low as 7% (2, 3).

Allogeneic hematopoietic stem cell transplantation (allo-SCT) is a potentially curative therapy for AML, that relies on the recognition and elimination of leukemic cells by donor T cells, as part of the graft versus leukemia effect (GVL) (4). However, allo-SCT is complicated by graft versus host disease (GVHD), a pathological state characterized by donor T cell-mediated lysis of liver, gut and skin cells, which is a main driver post-allo-SCT morbidity and mortality, with transplant-related mortality reaching roughly 20% (5). Thus, allo-SCT is recommended only when the risk of disease relapse and leukemia-related mortality exceeds its inherent risks.

The European Leukemia Net (ELN) risk stratification system integrates cytogenetic and molecular abnormalities to classify AML patients into favorable, intermediate, or adverse categories. By linking specific genetic profiles to long-term outcomes, the system guides therapeutic decisions: patients with favorable-risk disease are managed with chemotherapy alone, while those in intermediate- and adverse-risk group are considered prime candidates for allogeneic transplantation in first remission. In this way, the ELN classification can identify patients who are most likely to benefit from allo-SCT and those in whom its risks can be safely avoided (6).

The year 2022 marked a turning point in the field of AML, with the simultaneous publication of the fifth edition of the WHO Classification of Hematolymphoid Tumors and the revised, 2022, ELN recommendations. Both classifications emphasize the central role of molecular genetics in disease definition, risk stratification, and therapeutic decision-making, drastically modifying the clinical approach to AML (6, 7).

The prognostic system proposed by the ELN 2022 classification has not yet been systematically validated in Romanian AML cohorts. Only in recent years has a national program provided consistent access to immunophenotyping, cytogenetic, and molecular testing, enabling clinicians to apply these risk stratification tools in routine practice. At the same time, data from the World Health Organization highlight that Romania continues to carry a disproportionate burden of comorbid conditions such as cardiovascular disease, chronic obstructive pulmonary disease, asthma, tuberculosis, and depression-each of which may adversely affect AML outcomes (8). In addition, broader determinants of health reported by the WHO, including disparities in education, uneven access to medical services in rural regions, deficiencies in primary care, and some of the lowest public health expenditures in the European Union, are likely to further influence prognosis in this population (9). In this particular context, real-world data remain essential to assess how these global advances in the molecular and genetic classification and risk prognostication of AML translate into local practice.

MATERIALS AND METHODS

In this retrospective study, we have investigated 59 patients diagnosed with *de*

novo AML who received an allo-SCT in the Bone Marrow Transplant Department of the Regional Institute of Oncology, Iasi, Romania, between 2019 and 2024. The diagnosis of AML was established based on the 2022 WHO classification of myeloid neoplasms. Furthermore, the patients were risk stratified according to the 2022 ELN recommendations. This study was approved by the institutional ethics committee. The diagnosis of AML was confirmed by immunophenotyping according to EuroFlow standards (10). Conventional cytogenetic G-banding was performed using standard procedures. Four recurrent fusion transcripts (BCR-ABL1 p210, PML-RARA, RUNX1-RUNX1T1, CBFB-MYH11) were assessed by reverse transcriptase quantitative PCR. Molecular testing included NPM1 mutation analysis and FLT3-ITD detection. Complete remission (CR) was defined as the presence of <5% blasts in the bone marrow, absence of circulating blasts or extramedullary disease and recovery of the peripheral blood counts with an absolute neutrophil count $\geq 1.0 \times 10^9$/L and a platelet count $\geq 100 \times 10^9$/L, and no transfusion requirement. Pre-transplant patient fitness was assessed using the Hematopoietic Cell Transplantation Comorbidity Index (HCT-CI) score. Measurable residual disease (MRD) was evaluated by multiparameter flow cytometry and reverse-transcriptase polymerase chain reaction in patients in whom leukemia-associated phenotypes or traceable molecular anomalies were identified (10).

The statistical analysis was performed using the IBM SPSS Statistics 21.0 Software. The Chi square and Mann Whitney tests were used to analyze the associations between different variables. A p value <0.05 was considered to be statistically significant. Overall survival (OS) and disease-free survival (DFS) were estimated using the Kaplan Meier method. The log rank test was used for comparisons of Kaplan-Meier curves. OS was defined as the interval from the date of transplantation to death from any cause or to the date of last follow-up for surviving patients. DFS was defined as the time from transplant to relapse, death by any cause, or the date of the last follow-up.

RESULTS

We retrospectively analyzed 59 AML patients, diagnosed and classified as per the WHO 2022 and ELN 2022 classification and risk prognostication systems, who underwent allo-SCT at our center between 2019 and 2024. The baseline clinical and laboratory characteristics are presented in first table.

The median age at diagnosis was 44 years. The mean follow-up duration was 26 months. According to the 2022 WHO classification of myeloid neoplasms, the distribution of AML subtypes was as follows: AML with recurrent genetic anomalies- 19 cases (32.2%), AML with myelodysplasia related features- 8 cases (13.6%), AML defined by differentiation- 32 cases (54.2%). The detailed cytogenetic and molecular anomalies identified are presented in Table I. Notably, FLT3-ITD (Fms-like tyrosine kinase 3-internal tandem duplication) mutations were identified in 9 patients (15.3%), NPM1 (nucleophosmin 1) in 4 cases (6.8%), while the two mutations co-existed in 10 patients (16.9%). Based on the cytogenetic and molecular evaluation, patients were stratified according to the 2022 ELN classification into favorable (9 cases- 15.3%), intermediate (37 cases- 62.7%), and adverse risk groups (13 cases- 22%).

TABLE I.

Demographic, clinical, biological, cytogenetic, molecular and therapy response data of AML patients.

Chronic GVHD, (%)	12 (50%)

CR= complete remission, CSA= Cyclosporin A, Haplo= haploidentical donor, HCT-CI= hematopoietic stem cell transplantation comorbidity index, MAC= myeloablative conditioning, MRD= measurable residual disease, MSD= matched sibling donor, MUD= matched unrelated donor, N/A= not applicable, PTCy= post-transplant Cyclophosphamide, RIC= reduced intensity conditioning, SCT= stem cell transplant

89.8% of patients (n=53) received intensive chemotherapy with the standard "7+3" chemotherapy regimen as a backbone, while 10.2% (n=6) were treated with a less intensive induction regimen consisting of Venetoclax and Azacitidine. 84.7% (n=50) of patients achieved complete re-

mission following induction. Out of the patients achieving CR, 46.9% (n=23) presented MRD negativity after induction. Of the 59 patients, the majority (42 cases, 71.2%) underwent allo-SCT in CR1 (first CR), while 12 patients (20.3%) were transplanted in CR2. A smaller subset of 5 patients (8.5%) proceeded to transplant with progressive leukemia. The median time from diagnosis to transplant was 8 months.

All patients in our study group underwent allo-SCT at our center. The main transplant-related parameters are presented in second table. The CR rate at day+30 was 98.3%.

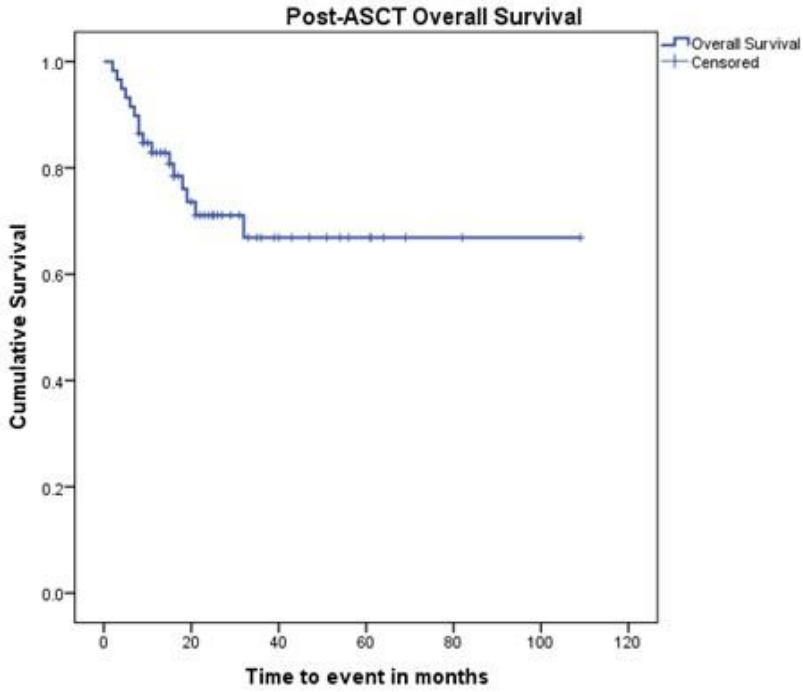

Fig. 1. Kaplan-Meier curve **for overall survival** in the entire study cohort.

At a median follow-up of 26 months, 43 patients (72.9%) were alive and 42 patients (71.2%) remained in remission. The median OS and DFS were not reached. The mean OS was 77.4 months (95% CI, 64.2-90.7), and the mean DFS was 77.6 months (95% CI, 64.9-90.2). The Kaplan-Meier estimated OS at 24 months was 74% (fig. 1), while the corresponding DFS rates were 74% at 12 months and 69% at 24 months (fig. 2).

Patients with post-transplant relapse (n = 17) had poor outcomes, but the occurrence of GVHD was strongly associated with improved survival. The median OS for patients without GVHD was 8 months (mean 11.2 months, 95% CI 6.1-16.3), with no long-term survivors. In contrast, patients who developed GVHD had a median OS of 18 months (mean 41.0 months, 95% CI 11.5-70.5), and two patients remained alive beyond 5 years.

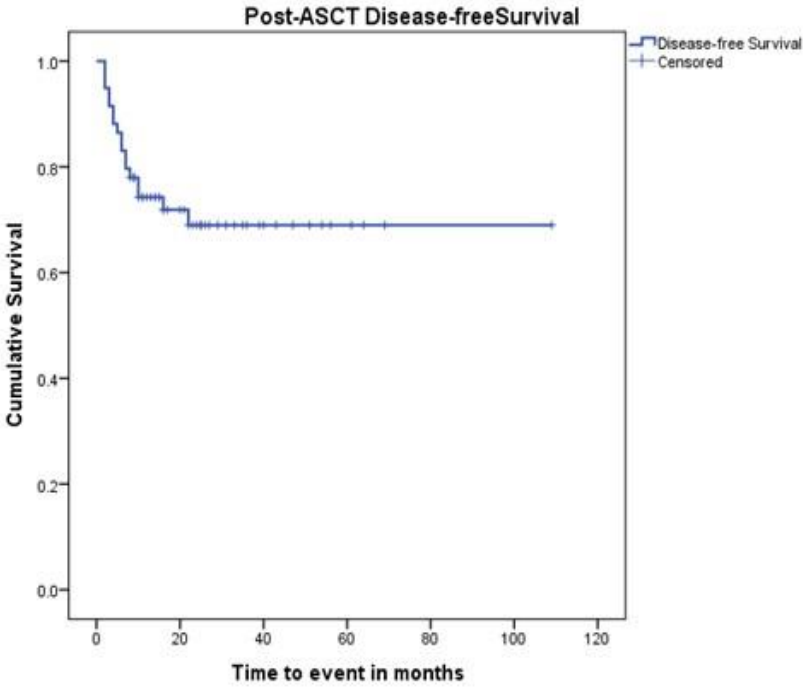

Fig. 2. Kaplan-Meier curve **for disease-free survival** in the entire study cohort.

On Kaplan-Meier analysis, OS and DFS differed significantly according to AML type, ELN 2022 risk, HCT-CI score, and disease status at transplantation (tab. III). Patients with *de novo* AML and those transplanted in CR achieved the most favorable outcomes, while secondary and therapy-related AML and active disease at transplant were associated with markedly inferior OS and DFS ($p < 0.05$ for all). OS also decreased significantly with increasing HCT-CI score (> 2; $p = 0.002$). MRD negativity, both pre-transplant and at days +30 and +90 post-SCT, correlated with improved OS, with the strongest effects observed at day +30 ($p = 0.007$) (fig. 3) and day +90 ($p = 0.014$) (fig. 4). DFS showed a similar but nonsignificant trend. GVHD occurrence was associated with longer OS ($p = 0.024$). No significant associations were found for age, WBC count, donor type, conditioning intensity, or molecular subtype (all $p > 0.05$). Other baseline parameters, including age at diagnosis, white blood cell count at presentation, the ECOG performance status, the type of AML according to the WHO classification, the NPM1 and FLT-3 status did not show a significant association with either OS or DFS in our cohort (all $p > 0.05$, log-rank test) (data not shown).

Out of the transplant-related parameters, we did not identify a significant association between OS or DFS and the donor type, the degree of HLA mismatch, the type of conditioning or immune suppressive regimen used (all $p > 0.05$, log-rank test) (data not shown).

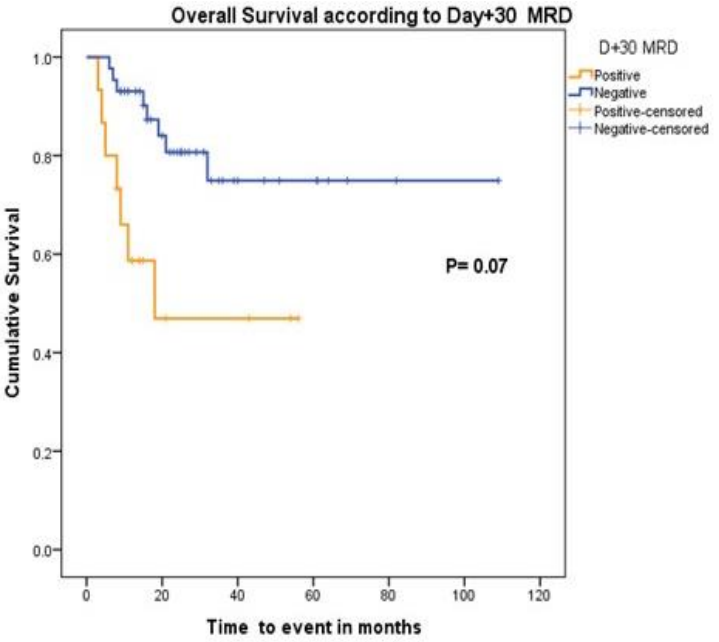

Fig. 3. Overall survival according to minimal residual disease status at day **+30** after allogeneic stem cell transplantation.

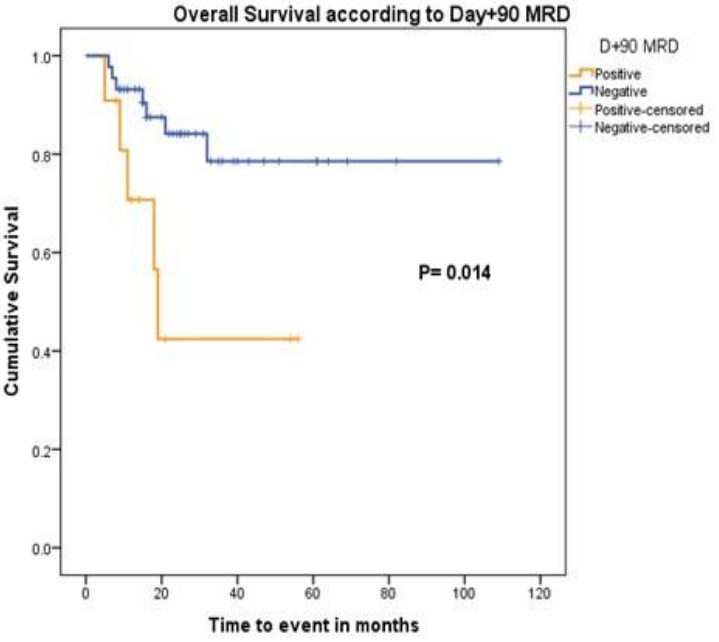

Fig. 4. Overall survival according to minimal residual disease status at day **+90** after allogeneic stem cell transplantation.

AML= acute myeloid leukemia, CR= complete remission, D=day, DFS= disease-free survival, ELN= European Leukemia Net, GVHD= graft versus host disease, HCT-CI= hematopoietic stem cell transplantation comorbidity index, MRD= measurable residual disease, NR= not reached, SCT= stem cell transplant

To identify independent predictors of OS and DFS, we further performed multivariable Cox proportional hazards regression including variables with statistical significance in univariate analysis. In the multivariable model for OS, MRD positivi-

ty at day +90 post-transplant emerged as the only independent adverse prognostic factor (HR = 12.5, 95% CI 1.6-99.5, p = 0.017), after adjusting for MRD at day +30 and GVHD occurrence. MRD positivity at day +30 showed a nonsignificant trend toward inferior survival (HR = 7.4, 95% CI 0.7-74.6, p = 0.09). Neither acute nor chronic GVHD retained statistical significance after adjustment.

For DFS, no independent predictors reached statistical significance in multivariable analysis. MRD positivity at day +90 remained associated with a numerically higher relapse hazard (HR = 11.5, 95% CI 1.4-91.9, p = 0.021), but the overall model fit did not reach significance (LR χ^2 = 4.6, p = 0.20). Chronic GVHD and MRD at day +30 showed no significant effect.

The AML type, pre-transplant disease status, and HCT-CI score were not retained as significant predictors of either OS or DFS in the multivariable models.

At a median follow-up of 26 months, the CIR was 28%, while NRM remained low (2%). The majority of deaths were relapse-related, underscoring disease recurrence as the principal cause of post-transplant mortality in our study cohort.

DISCUSSION

Allo-SCT represents an essential tool in the management of AML, offering the only curative option for high-risk patients. The integration of dynamic prognostic markers such as MRD into pre-transplant individualized risk stratification and post-transplant monitoring strategies further reduces the risk of relapse, by facilitating pre-emptive, MRD-driven therapeutic interventions.

Nevertheless, several reports have questioned the prognostic applicability of cytogenetic and molecular risk factors in patients from developing countries (11,12), including Romania, where socio-economic disparities, uneven access to specialized care, and limited molecular diagnostic infrastructure may influence outcomes (9). In this context, we aimed to evaluate the relevance of the 2022 ELN risk classification system and the prognostic contribution of allo-SCT in a real-world cohort of AML patients treated at the Iași Regional Institute of Oncology.

In our study cohort, the AML type and the disease status at the moment of allo-SCT had a significant impact on post-transplant outcomes. According to the 2022 ELN denominators of disease ontogeny, patients with *de novo* AML achieved the best long-term outcomes. On the other hand, those diagnosed with secondary or therapy-related AML had markedly inferior OS and DFS despite undergoing allo-SCT. These findings evidence that the adverse biological features and treatment resistance associated with antecedent hematologic disorders such as myelodysplastic syndromes or therapy-related AML might not be fully overcome by the allo-SCT procedure. Similar findings have been reported in larger studies, where the disease ontogeny and pre-transplant remission status remained independent predictors of relapse and survival (13,14). Early referral and timely transplantation in molecular remission remain therefore very important, particularly for patients with secondary or therapy-related AML.

Regarding DFS, although a numerical gradient was observed across the ELN 2022 risk groups, the differences did not reach statistical significance. This is most likely explained by the relatively small number of patients in each subgroup, limiting the statistical power of the analysis.

Additionally, the HCT-CI score provided relevant prognostic information regarding survival in our study group, as patients with higher HCT-CI score had significantly inferior OS, confirming that comorbidity burden remains a major determinant of post-transplant mortality. This finding is consistent with prior studies showing the predictive value of HCT-CI for post-allo-SCT outcomes in AML (15,16).

Moreover, in our cohort, patients who developed chronic GVHD had superior OS compared to those with acute or overlap GVHD. This finding likely reflects the protective graft-versus-leukemia effect associated with chronic GVHD, which reduces relapse risk despite its associated morbidity. By contrast, acute and overlap GVHD contributed to inferior outcomes due to early transplant-related mortality and the combined toxicities of both entities.

While both MRD positivity at day +30 and day +90 were associated with inferior survival, persistence of MRD at day +90 identified a particularly poor-risk subset, reflecting failure of GVL activity to eradicate residual disease and indicating imminent relapse.

In multivariable analysis, only MRD positivity at day +90 remained an independent predictor of inferior OS. This finding is consistent with previous reports showing that later post-transplant MRD monitoring can predict relapse risk and long-term outcomes in AML, but also facilitate timely therapeutic interventions, such as donor lymphocyte infusions (DLI) (17,18). The absence of independent predictors for DFS likely reflects the limited event number and interdependence between relapse and transplant-related factors.

Finally, in our cohort, patients experiencing relapse after allo-SCT had a median OS of 11 months, a figure that compares favorably with international registry data. Large series from the EBMT and CIBMTR typically report median survivals of only 3-6 months following post-transplant relapse, with fewer than 15% of patients alive at 2 years despite salvage interventions such as DLI. While our results confirm that relapse after allo-SCT remains a severe event, the observed median OS suggests that intensive and structured management may extend survival even in resource-limited settings. This finding underscores the potential benefit of complex post-relapse therapeutic strategies and highlights that outcomes achieved in our center are not markedly inferior to those reported in higher-resource contexts.

CONCLUSIONS

Allo-SCT remains a curative therapy in AML, particularly for intermediate and adverse ELN risk patients. In our study, survival was strongly influenced by disease status and MRD at transplant, confirming the prognostic importance of achieving pre-allo-SCT deep remission. Secondary and therapy-related AML, high HCT-CI scores, and active disease at transplantation were associated with inferior outcomes. These findings emphasize the need for timely, MRD-driven transplant referral and for expanding transplant capacity in Romania to optimize long-term outcomes of leukemia patients.

THE ORAL-SYSTEMIC INTERFACE IN SEVERE MENTAL ILLNESS: A COMPARATIVE ANALYSIS OF DIETARY PRO-OXIDANT PATTERNS AND BIO-CLINICAL INTERSECTIONS IN PATIENTS WITH SCHIZOPHRENIA (Abstract): This study aims to investigate the nutritional pathways and lifestyle behaviors that bridge psychiatric symptomatology and oral pathological outcomes, specifically focusing on the role of dietary-induced oxidative stress in patients with schizophrenia compared to a healthy control group. **Materials and methods:** A comparative cross-sectional analysis was conducted on 40 participants (20 patients with schizophrenia and 20 demographically matched controls). Nutritional habits, antioxidant intake and pro-inflammatory food frequencies were assessed using validated questionnaires. Data were statistically analyzed to identify significant divergences in consumption patterns. **Results:** Patients with schizophrenia showed a significantly lower intake of dietary fiber compared to controls (1.65 ± 1.51 *vs*. 2.80 ± 1.92, $p = 0.041$). Significant increases were observed in the consumption of fried foods ($p = 0.029$) and processed items ($p = 0.048$). Although antioxidant and fruit intake followed a downward trend, they did not reach the significance threshold, contributing to a documented pro-oxidant dietary environment. **Conclusions:** The results confirm a compromised "gut-brain-mouth" axis in schizophrenia. The dietary-induced pro-oxidant environment serves as a systemic driver for oral degradation, necessitating integrated psychiatric and dental management. **Keywords:** SCHIZOPHRENIA, ORAL HEALTH, OXIDATIVE STRESS, NUTRITIONAL PSYCHIATRY, DIETARY PATTERNS.

INTRODUCTION

Schizophrenia remains one of the most challenging conditions in modern psychiatry, not only due to its debilitating cognitive and emotional symptoms but also because of the significant somatic burden in imposes patients.

Beyond the neurological manifestations, recent research has shifted the focus toward the "whole-body" impact of the disorder, highlighting a state of chronic, low-grade systemic inflammation (1). One of the most

critical yet frequently overlooked components of this physical decline is oral health, which acts as a bio-indicator for the overall psychological status of the patient (2).

The relationship between severe mental illness and dental pathology is multifaceted. Historically, poor oral outcomes in these patients were attributed solely to suboptimal hygiene or the side effects of antipsychotic medication, such as xerostomia (3). However, contemporary perspectives, including the "gut-brain axis" theory, suggest that the pathobiological intersections are much deeper. The nutritional status of patients with schizophrenia often reveals a profound imbalance, characterized by preference for high-caloric, nutrient-poor diets (4). This dietary pattern does not merely contribute to metabolic syndrome but also fuels a pro-oxidant environment that accelerates tissue destruction in the oral cavity.

The oral microenvironment is highly sensitive to the body's antioxidant defense mechanisms. When dietary intake of polyphenols and vitamins is replaced by refined sugars and saturated fats, the resulting oxidative stress triggers an inflammatory cascade in the periodontal tissues (5). Therefore, understanding the dietary choices of these patients is not just a matter of nutritional counseling, but a necessity for preventing irreversible dental damage.

Despite the clear clinical links, there is a scarcity of integrated data that correlate specific food frequency patterns in psychiatric patients with their systemic inflammatory risk. This study, conducted in the Iasi region, provides a foundation for a more holistic approach in both dental and psychiatric clinical practice. By examining these intersections, we aim to demonstrate that oral health management must become a core component of the integrative treatment of schizophrenia.

MATERIALS AND METHODS

This comprehensive, cross-sectional study was conducted between December 2024 and January 2025 in Iasi, Romania. The research focused on evaluating the nutritional architecture and lifestyle factors of patients with severe mental illness in relation to their potential impact on oral health. The study population consisted of two distinct cohorts: a clinical group (n=20) comprising patients diagnosed with schizophrenia according to the DSM-V criteria and a healthy control group (n=20) recruited from the general population with no history of psychiatric or significant systematic disorders.

Inclusion criteria for the clinical group were: a confirmed diagnosis of schizophrenia, age over 18 years and the cognitive ability to provide informed consent and complete the assessment tools. Exclusion criteria included the presence of acute medical emergencies, pregnancy or current participation in intensive nutritional intervention programs. The control group was age-matched to ensure demographic comparability across the 18-60 age range.

The study was conducted in accordance with the Declaration of Helsinki. All participants were informed about the nature of the research, the confidentiality of the data and their right to withdraw at any time. Written informed consent was obtained from each participant or, where applicable, their legal guardians.

A comprehensive digital survey was employed to gather data on demographics, clinical history and dietary habits. The nutritional assessment was based on a modified Food Frequency Questionnaire (FFQ),

specifically designed to capture the "patho-biological intersections" between dietary intake and systemic inflammation. Participants reported their consumption frequency for various food groups over the previous month using a Likert-type scale ranging from "Never" to "Daily".

The survey focused on three specific dietary domains:

1. Protective factors: Frequency of intake for fresh fruits, vegetables, dietary fibers and antioxidant-rich foods (e.g, berries, nuts, leafy greens).
2. Pro-inflammatory and cariogenic factors: Consumption of refined sugars (candies, pastries), carbonated beverages, fast food and deep-fried items.
3. Lifestyle and comorbid factors: Prevalence of smoking, alcohol consumption and the use of dietary supplements or probiotics.

Quantitative data derived from the frequency scales were converted into numerical values to facilitate comparative analysis. Frequency scores were assigned based on consumption regularly (e.g, Daily = 7; 2-3 times/week = 2.5; weekly = 1; Never = 0). Descriptive statistics, including means and percentages distributions were calculated for each dietary variable. The significance of differences between the schizophrenia group and the control group was evaluated using independent t-test or Mann-Whitney U test, depending on the data distribution. A *p-value* less than 0.05 was considered statistically significant. All analyses were performed using Microsoft Excel, ensuring a rigorous interpretation of the nutritional gaps identified.

RESULTS

The study cohort consisted of 40 participants, equally divided between patients with schizophrenia (n = 20) and healthy controls (n = 20). The demographic analysis showed that the psychiatric group was predominantly composed of individuals in the 31-60 age range (85%), with a higher prevalence of unemployment (90%), reflecting the social burden of the disease. In contrast, the control group was more diversely distributed across age groups and employment statuses.

Specifically, the intake of dietary fiber was significantly lower in patients compared to controls (1.65 ± 1.51 *vs.* 2.80 ± 1.92, p = 0.041), representing a 41% reduction. Similarly, consumption of fresh fruits, vegetables and antioxidant-rich foods showed a marked downward trend in the psychiatric cohort, although these did not reach statistical significance (tab. I).

TABLE I.

Comparative analysis of protective dietary factors

Nutritional Factor	Control Mean (± SD)	Schizophrenia Mean (± SD)	*p-value*
Fruits and Vegetables	2.65 (± 2.00)	1.67 (± 1.42)	0.083
Antioxidant-rich Foods	2.27 (± 1.77)	1.42 (± 1.47)	0.107
Dietary Fiber	2.80 (± 1.92)	1.65 (± 1.51)	0.041*

Note: Scores calculated on a scale of 0 (Never) to 7 (Daily); SD = Standard Deviation;
** indicates statistical significance (p < 0.05 based on Independent T-test).*

The nutritional gap is visually represented in the comparison of protective factors (fig. 1).

Consumption of fried foods and saturated fats was nearly double in patients with schizophrenia (2.45 ± 1.75) compared to control group (1.47 ± 0.80, p = 0.029). This pro-inflammatory trend was also evident in the consumption of refined sugars and carbonated beverages (fig. 2).

Processed food consumption was also significantly higher in the psychiatric group (1.25 ± 1.28 *vs.* 0.50 ± 1.03, p = 0.048), while the increased intake of refined sugars (2.35 *vs.* 1.82) contributes to the overall cariogenic potential (tab. II).

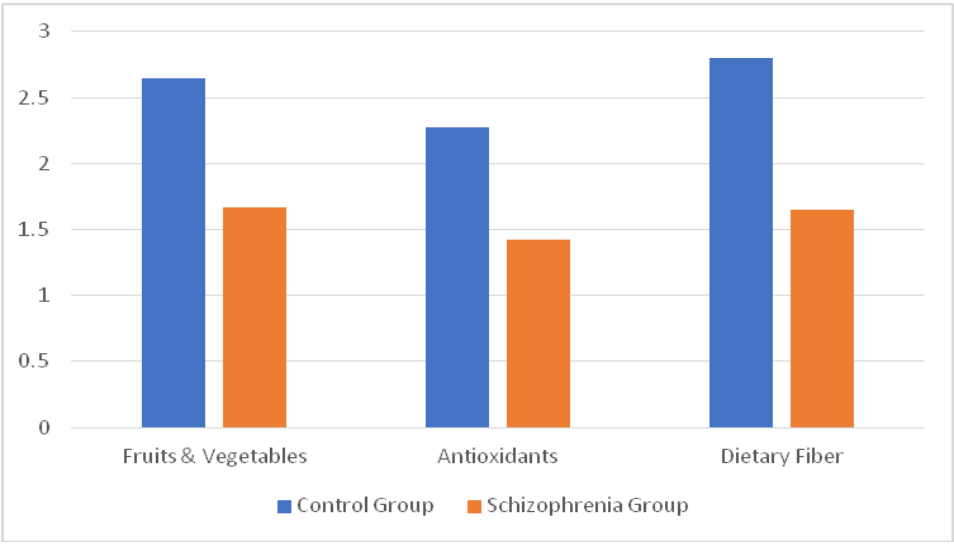

Fig. 1. Protective factors

TABLE II.

Pro-inflammatory and cariogenic risk profile

Risk Factor	Control Mean (± SD)	Schizophrenia Mean (± SD)	*p-value*
Fried Foods and Saturated Fats	1.47 (± 0.80)	2.45 (± 1.75)	0.029*
Refined Sugars (Sweets)	1.82 (± 1.55)	2.35 (± 1.28)	0.249
Carbonated Beverages	1.27 (± 1.01)	1.95 (± 1.91)	0.170
Processed Foods	0.50 (± 1.03)	1.25 (± 1.28)	0.048*

*Note: SD = Standard Deviation; * indicates statistical significance (p < 0.05 based on Independent T-test).*

The escalation of pro-inflammatory dietary choices in the psychiatric group is evident (fig. 2).

Lifestyle variables further compounded these risks. Although smoking frequency was high across both groups, alcohol consumption frequency was more than double in the schizophrenia group (0.90 *vs.* 0.42).

The cumulative data indicate that patients with schizophrenia live in a "pro-oxidant nutritional environment", which, in the absence of adequate antioxidant defense, serves as a primary driver for oral tissue degradation.

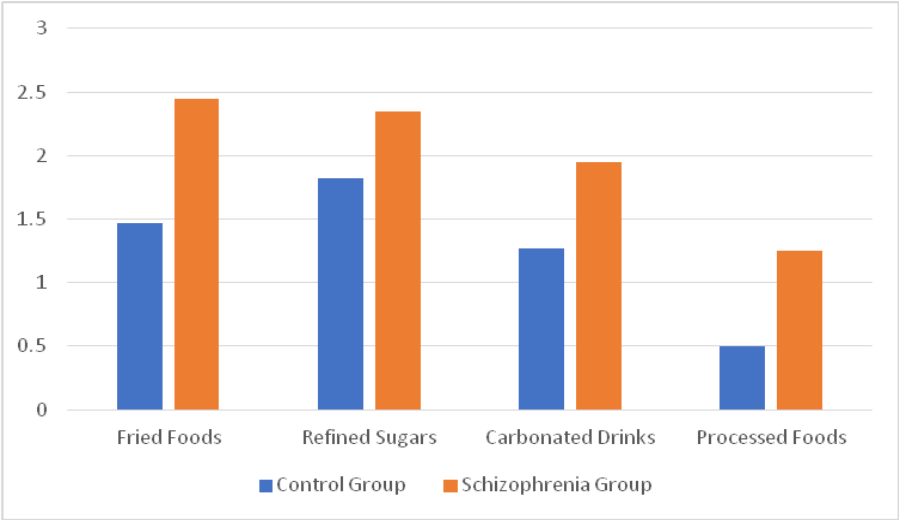

Fig. 2. Risk Factors

DISCUSSION

The nutritional architecture of patients with schizophrenia in the Iasi region reveals a significant systemic vulnerability. Our results demonstrate a profound "nutritional gap" characterized by a critical deficit in antioxidants and fiber ($p = 0.041$), coupled with a nearly twofold increase in the consumption of pro-inflammatory foods like fried fats ($p = 0.029$) and refined sugars (tabs. I, II). This dietary shift does not merely represent a lifestyle preference but serves as a primary driver for oral-systemic degradation.

The significant reduction in antioxidant intake observed in our cohort is a key finding that aligns with current models of "Nutritional Psychiatry". Previous work by our group has extensively examined the intersection of molecular markers and clinical outcomes, emphasizing that the gap between laboratory findings and patient care can only be bridged through an oxidative stress-centered approach (6). This is particularly relevant in oral medicine, as periodontal tissues are highly sensitive to the balance between reactive oxygen species (ROS) and antioxidant defenses. When protective factors are absent, as seen in our data, the oral mucosa becomes vulnerable to the same inflammatory cascades observed in other chronic conditions. For instance, the therapeutic potential of natural polyphenolic extracts has been documented in mitigating oxidative damage in gastrointestinal models (7), suggesting that the systematic absence of such compounds in the diet of psychiatric patients directly impairs their capacity to resolve periodontal inflammation.

Furthermore, the high prevalence of fried food and saturated fat consumption in the schizophrenia group (+0.98 difference, $p = 0.029$) points toward a systemic pro-inflammatory status. Research conducted by our team in related medical fields highlights that chronic systemic stressors often manifest through significant structural and functional changes in

organ systems, such as increased tissue stiffness in extrahepatic cholestasis (8) or the development of small bowel malignancies (9). While these studies involve different anatomical sites, they establish a critical principle of "tissue vulnerability" under chronic stress. In the context of dental medicine, this suggests that the oral environment in schizophrenia is not an isolated compartment but part of a wider pathobiological intersection where systemic inflammation, driven by poor nutrition, accelerates the breakdown of tooth-supporting structures.

This metabolic complexity is further highlighted when managing high-risk clinical populations. Our experience with complex chronic conditions, such as HCV cirrhosis in elderly patients (10), has taught us that therapeutic safety and efficacy are inextricably linked to the patient's underlying systemic resilience. Similarly, the dental management of a patient with schizophrenia cannot succeed through local hygiene alone. The high intake of carbonated beverages and refined sugars found in our study mirrors findings from international cohorts, where psychiatric patients are reported to have significantly higher rates of decayed, missing and filled teeth (DMFT) due to dietary cariogenicity (11, 12).

Our findings on the deficit of fruits and vegetables are consistent with studies by Vetrani *et al*. (13) and Dipasquale *et al*. (4), which identified that patients with severe mental illness often consume diet types that are high in energy but low in essential micronutrients. This nutritional pattern has been linked to increased levels of C-reactive protein (CRP) and other pro-inflammatory cytokines (14). In the oral cavity, this systemic inflammation is exacerbated by psychological stress, which has been shown to induce oxidative DNA damage in salivary glands (15).

Moreover, the "gut-brain-mouth" axis suggested by our data is supported by recent research into the oral microbiome. Studies by Comparelli *et al*. (16) and Gurbuz *et al*. (17) have demonstrated that the dietary habits of schizophrenic patients alter the oral microbial ecosystem, favoring the growth of periodontal pathogens. When combined with the high frequency of smoking observed in our study, this creates a "synergistic insult" to the oral tissues. The lack of dietary fiber found in our patients ($p = 0.041$) further complicates this, as fiber is known to modulate systemic inflammation through the production of short-chain fatty acids (18), which play a role in maintaining the integrity of both the gut and the oral mucosal barriers (19, 20).

Ultimately, the nutritional gap identified in this study advocates for a multidisciplinary clinical shift. Dental professionals must move beyond the "drilling and filling" paradigm and recognize the psychiatric patient's dietary status as a primary clinical marker. Integrating antioxidant monitoring and nutritional counseling into the standard psychiatric protocol is essential to mitigate the systemic and oral complications of the disease.

However, certain limitations of the present study must be acknowledged, such as the relatively small sample size and the reliance on self-reported dietary data, which may be subject to recall bias. Furthermore, while the identified nutritional patterns strongly suggest a pro-oxidant state, longitudinal studies incorporating

direct biochemical markers of oxidative stress are required to establish a definitive causal link between specific dietary deficits and the progression of periodontal destruction in this population.

CONCLUSIONS

The results of this study confirm a profound nutritional imbalance in patients with schizophrenia, characterized by a statistically significant deficit in dietary fiber ($p = 0.041$) and a marked escalation in the consumption of pro-inflammatory foods, such as fried fats ($p = 0.029$) and processed products ($p = 0.048$). This "nutritional gap" creates a systemic pro-oxidant environment that directly compromises oral mucosal integrity and periodontal health. Our findings suggest that the oral cavity acts as a clinical mirror for the metabolic disturbances associated with severe mental illness. Consequently, managing these patients requires a multidisciplinary shift that integrates nutritional counseling and antioxidant monitoring into standard psychiatric and dental care to mitigate the systemic drivers of oral degradation.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest and they received no specific funding regarding this scientific research.

THE ROLE OF SMOOTH MUSCLE AND SUBMUCOSAL GLANDS IN THE AIRWAY REMODELING IN ASTHMA (Abstract): **Aim:** Bronchoconstriction, chronic inflammation, and airway remodeling are the main factors associated with the airflow restriction in patients with asthma. Airway remodeling includes all morphological changes of the bronchial wall in asthma, contributing to clinical manifestations and progressive loss of lung function. The aim of this study was to evaluate the morphological changes associated with airway remodeling, being focused on submucosal glands and muscular tissue, in a group of asthmatic patients. **Materials and methods:** We performed a retrospective analysis on 38 patients with a history of bronchial asthma, with different degrees of severity. All patients were classified according to the latest Global Initiative for Asthma (GINA) criteria and underwent a fibro bronchoscopy examination associated with biopsy of tissue samples for microscopy. **Results:** The study included 38 asthmatic patients, with a female predominance (68.42%) and a mean patient age of 49±16 years. The microscopic exam revealed an increase of smooth muscle and submucosal glandular areas in asthmatic patients in comparison to healthy persons and a close correlation with the asthma severity, reflected by FEV1 values. The statistical analysis showed an inverse correlation between FEV1 (%) values and muscular ($r = -0.8997$, $p < 0.001$) and glandular area hypertrophy ($r=-0.887$, $p < 0.01$). **Conclusions:** The increase of muscle and submucosal glands areas, as part of the airway remodeling process, represents a specific pathological feature mainly associated with severe forms of asthma, being correlated with lung function restriction. **Keywords:** ASTHMA, BRONCHIAL SMOOTH MUSCLE, SUBMUCOSAL GLAND, FEV1.

INTRODUCTION

Airway hyper-responsiveness, added to chronic airway inflammation and reversible airflow limitation, are the most important features of asthma (1). These changes occur as a result of bronchial wall remodeling, leading to its thickening (1, 2). Morphologically, these features are represented by epithelial cell damage, goblet cell hyperplasia, basement membrane thickening with subepithelial fibrosis, edema and neoangiogenesis in the lamina propria, submucosal glandular hypertrophy, and smooth muscle hyperplasia or hypertrophy (2- 4).

Variations of the airway wall thickness have been correlated with lung function and they may therefore reflect the severity of asthma (5). Airway hyper-reactivity is also determined by the contractile activity of bronchial smooth muscle, which is the principal effector in bronchoconstriction. Notably, chronic inflammation of the bron-

chial wall plays a central role in modulating both bronchial smooth muscle activity and the other structural changes that characterize airway remodeling, including mucus hypersecretion (3).

In recent years, numerous studies have focused on the mechanisms underlying bronchial smooth muscle and submucosal glandular hypertrophy in asthmatic patients, with the aim of identifying novel therapeutic targets (1). Thus, increased bronchial wall thickness has been associated with impaired lung function and reduced spirometry parameters, such as Forced Expiratory Volume in 1 second (FEV1) and the FEV1/Forced vital capacity (FVC) ratio, particularly in uncontrolled (severe) asthma (6). Corticosteroid therapy in asthmatic patients has been also demonstrated to reduce the bronchial wall inflammation, with a limited effect on submucosal glandular hypertrophy and bronchial smooth muscle hypertrophy (6, 7). However, the molecular mechanisms underlying submucosal glandular and smooth muscle hypertrophy or hyperplasia associated with airway remodeling are extremely complex and remain only partially deciphered (6, 7).

In this context, this study aims to demonstrate the airway remodeling and its relationship with spirometry parameters in a group of asthmatic patients, being focused on bronchial glandular and smooth muscle hypertrophy or hyperplasia.

MATERIALS AND METODS

The study group included 38 adult asthmatic patients diagnosed in the Specialty Ambulatory of the Pneumology Clinic Hospital, Iasi, Romania. All patients were non-smokers (totally non-smoker or former occasional smoker), receiving treatment with inhaled corticosteroids, without other chronic or acute lung diseases, and able to adequately and correctly perform a spirometry test. The inability to adequately and correctly perform a spirometry test along with the presence of other chronic or acute lung diseases or the patient declaring himself a smoker were used as exclusion criteria from the study group. Patients' history, chest X-ray, and spirometry assessment using FEV1 were used to classify the asthmatic patients according to the last GINA classification (8). Subsequently, a fibro bronchoscopy exam was performed with the collection of five to seven tissue fragments for each case, to limit the risk of insufficient material or inconclusive results (2, 9). The collected tissue fragments were fixed in buffered formalin, processed for paraffin embedding, and stained with Hematoxylin & Eosin and Goldner-Szekely trichrome staining.

The thickness of the bronchial smooth muscle and submucosal glandular areas was assessed using a semi-quantitative scoring system [score 1 (+) = almost normal, score 2 (+) = moderate increase and score 3 (+++) = severe increase] as the distance between the epithelial layer/basal membrane and smooth muscle or submucosal glandular areas at 4 x magnification, by two independent pathologists (10, 11). The control group included two patients without asthma symptoms, which have been investigated for tumor suspicion.

The proliferation potential of bronchial muscle cells and submucosal glandular areas was evaluated by Ki-67 index, using immunohistochemistry (clone MIB-1; Dako), according to the manufacturer protocol.

The study was conducted in accordance with the Declaration of Helsinki for research involving human subjects and patients were included in the study group based on informed consent.

The statistical analysis was performed using *SPSS version 25* (IBM, Armonk, NY, USA). Associations between continuous variables were assessed using Pearson's and Spearman's correlation coefficients and linear regression analysis was performed to estimate the slope of the relationships. Statistical significance was set at $p < 0.05$.

RESULTS

Following clinical examination and spirometry testing, the 38 patients included in the study were classified into three severity degrees, according to the GINA 2025 criteria: 17 cases (44.73%) of well-controlled (intermittent/mild) asthma, 16 cases (42.10%) of partially controlled (moderate) asthma, and five cases (1.31%) of uncontrolled (severe) asthma. The mean value of FEV1 (% of predicted) was 78.3±22.6%, the lowest mean values being registered in the uncontrolled (severe) asthma cases (43.6±10.8), followed by partially controlled asthma (66.7±6.2%), and well-controlled asthma (100.4 +10.1%).

The median age of asthmatic patients was 49±16 years (range: 22-72), most of cases being included in the 6th and 7th decades of life (26.32% each), followed by the 3rd decade (21.05%), the 4th decade with 7.89% cases, and the 8th decade with 2.63% cases. The study population was predominantly female (n = 26; 68.42%) and the mean age was higher among women (52±15.6 years) than in men (42.4±15.5 years). The majority of patients were from urban areas (n = 28; 73.68%), with only 10 patients (26.32%) from rural areas, and most had a duration of bronchial asthma between 15 and 20 years.

A bronchial wall thickening due to smooth muscle hypertrophy or hyperplasia (score 3) was detected in four cases of uncontrolled asthma, while a moderate smooth muscle hypertrophy or hyperplasia has been registered in 16 cases (15 cases of partially uncontrolled asthma and one case of uncontrolled asthma). The remaining cases exhibited a near-normal appearance of the muscle layer (figs. 1 and 2). Ki-67 immunoexpression was negative in all cases, except in two cases of uncontrolled asthma, with weak and rare positivity (figs. 3 and 4).

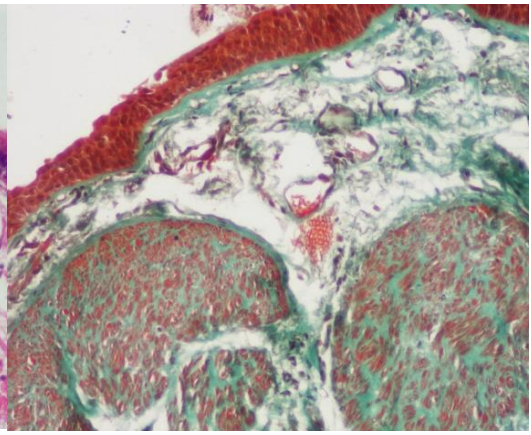

Fig. 2. Significant increase of smooth muscle surface area in uncontrolled asthma, Goldner-Szekely trichrome, 4x

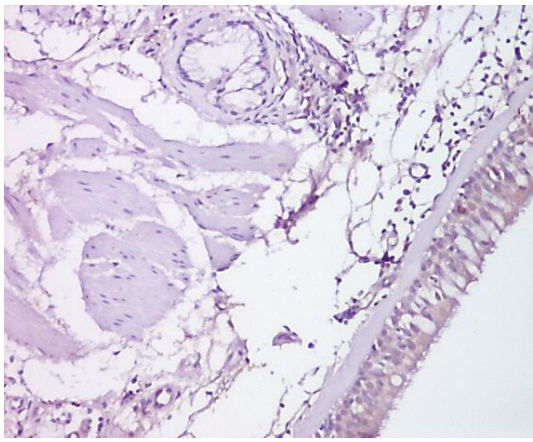

Fig. 3. Negative Ki-67 immunoexpression in bronchial muscle cells in partially controlled asthma, 10x

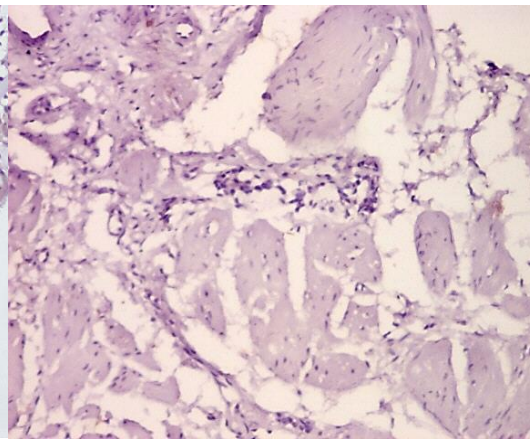

Fig. 4. Ki-67 immunoexpression: weak and rare positivity of bronchial muscle cells in uncontrolled asthma, 10x

A significant submucosal glandular hypertrophy has been also registered in all patients with uncontrolled asthma and in two cases of partially uncontrolled asthma. Near-normal glandular areas have been observed in 16 cases (42.10%) of well-controlled asthma, while a moderate increase of submucosal glandular area of the bronchial wall has been observed in 15 cases (39.47%) (14 cases of partially controlled asthma and one case of well-controlled asthma) (figs. 5 and 6). A negative Ki-67 immunoexpression of the bronchial glandular area has been observed in all biopsies of asthmatic patients (figs. 7 and 8).

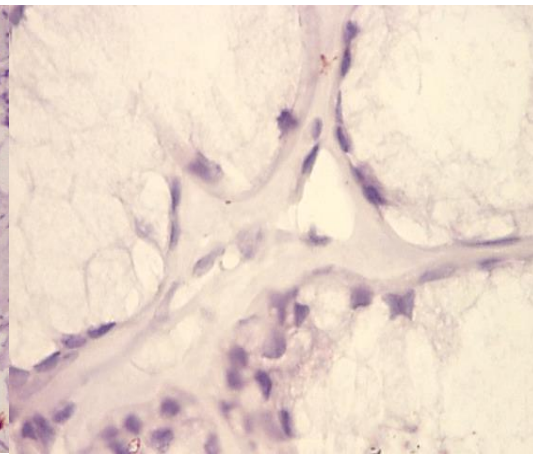

Fig. 8. Negative Ki-67 immunoexpression in bronchial glands in uncontrolled asthma, 40x

The statistical analysis applied to evaluate the association between muscle mass hypertrophy and bronchial asthma severity revealed a Spearman correlation coefficient of rho = 0.93, $p < 0.01$ (tab. I). Moreover, the bronchial wall muscular hypertrophy was mainly noted in patients with low FEV1 values, this inverse association between FEV1(%) values and muscle mass hypertrophy or hyperplasia of bronchial wall being supported by the high value of the correlation coefficient ($r = -0.8997$, $p < 0.001$) and confirmed by a significant negative regression slope (fig. 9).

Regarding submucosal glandular area hypertrophy, the statistical analysis revealed a strong positive correlation between asthma severity and the glandular area hypertrophy of the bronchial wall (Spearman's rho = 0.92, $p < 0.01$) (tab. II). A significant inverse correlation between FEV1 (%) values and the submucosal glandular area hypertrophy was observed ($r=-0.887$, $p < 0.01$), which was further supported by linear regression analysis (fig. 10).

Mean FEV1 (%) values were higher in asthmatic patients with a near-normal glandular area and lower in cases with marked submucosal glandular hypertrophy.

DISCUSSION

Bronchial wall remodeling is a consequence of chronic airway inflammation in asthma, a feature which was also observed in other chronic inflammatory diseases (12-15). As a part of the airway remodeling process, an abnormal increase of submucosal glandular and smooth muscle bronchial areas has been mainly detected in severe forms of asthma, features modulated by IL-5, IL-13, and other non-T2 cytokine-dependent-mechanisms (1, 16, 17). In this context, a 50-100% thickening of the bronchial wall was observed in patients with fatal asthma, compared to patients with non-fatal asthma, this increase being correlated with pulmonary functional status (1).

Although bronchial submucosal gland hypertrophy has been demonstrated as a key contributor to mucus hypersecretion, together with goblet cell hyperplasia of the respiratory epithelium (1), the origin and the molecular mechanisms underlying the thickening of the airway smooth muscle layer remain partially elucidated (6, 18).

In recent decades, different studies have explored the potential proliferation of muscle cells in the airway wall in asthmatic patients, with contradictory results. In this context, an increased proliferative capacity of airway muscle cells was observed in asthmatic patients compared to control individuals, especially in the case of partially uncontrolled or uncontrolled asthma (19, 20), while other studies suggest that the thickening of the asthmatic bronchial smooth muscle layer is not associated with active muscle cells proliferation (21, 22). A very limited proliferative activity of airway muscle cells was observed in uncontrolled asthmatic cases in our study, suggesting that the increase of muscle thickness involves other mechanisms, such as hypertrophy or cellular differentiation or trans differentiation. According to recent data, myoblasts, mesenchymal stem cells, epithelial cells, and pericytes may contribute to the thickening of the bronchial muscle mass by migration and trans differentiation into smooth muscle cells, mainly in severe asthma (23, 24). Furthermore, glucocorticoid administration may reduce the microvascularisation in the lamina propria and may decrease the basement membrane thickness in asthmatic cases (25, 26). However, their effect on the decrease of the size of the smooth muscle area associated with airway wall remodeling in asthmatic patients is limited (25, 26). Our results reinforce this data, showing that among asthmatic patients receiving chronic inhaled corticosteroid therapy, bronchial muscle area was significantly increased and correlated with asthma severity, as indicated by reduced FEV1 values. Furthermore, a significant increase of the smooth muscle area was observed in patients with uncontrolled asthma compared to partially controlled or well-controlled asthma patients, which is consistent with other studies (10, 27, 28). In this context, a mean bronchial muscle area of 0.24 ± 0.03 mm^2 was registered in patients with uncontrolled asthma compared to partially controlled patients (0.05 ± 0.01 mm^2) in a group of 28 asthma cases (10). In addition, smooth muscle cells accounted for 27% of the subepithelial tissue, in a group of 24 children with asthma (28), a proportion that can increase up to 40% in patients with uncontrolled asthma (27). All these data support the direct relationship between asthma severi-

ty, reflected by reduced spirometry parameters, and increased muscle area associated with the bronchial wall remodeling process that can occur in asthmatic patients, as also observed in our study.

Another morphologic component of the airway remodeling process in asthma is the submucosal glandular area hypertrophy (1). Goblet cell hyperplasia added to hypertrophy of bronchial glandular area may lead to a three-fold increase in mucin secretion in asthma (17, 29). Mucus hypersecretion induces "mucus plugs" occurrence that is associated with airflow obstruction (1, 29). Thus, a 30-fold increase in goblet cell count (30) and a greater increase in submucosal glandular area in the bronchial wall was observed in fatal asthma patients compared to those with non-fatal asthma ($p=0.003$) (31). In addition, mucus hypersecretion due to increased bronchial submucosal glandular areas has been demonstrated to be associated with asthma attacks (30). Thus, an increased mucous gland area and percentage of the relaxed lumen area occupied by mucus have been detected in asthma cases ($p < 0.05$) compared with healthy patients (32), with mucus hypersecretion being also partially related to goblet cell hyperplasia even in well-controlled asthma (33, 34). Moreover, mucus hypersecretion has been detected to be inversely correlated with FEV1 (Spearman's rho = -0.51, $p < 0.001$) and FEV1/FVC ratio (Spearman's rho = -0.54, $p < 0.001$) in a large cohort of asthmatic cases (35), data which are consistent with our observation.

Although an increased two- to four-fold compare to controls of the submucosal gland area in asthma has been detected, the glandular hypertrophy is not a constant morphologic feature in all asthmatic patients (36). This feature is in accordance with our results, showing a near-abnormal appearance of the submucosal glandular area in most cases. Moreover, the increased airway submucosal glandular area is due to hypertrophy of the mucous glands, demonstrated by the Ki-67 negative immunoexpression in all cases examined tissue fragments. Given their impact on lung function, preventing mucus plug formation driven by mucus hypersecretion represents a new therapeutic strategy to prevent airflow obstruction, particularly in patients with uncontrolled asthma.

CONCLUSIONS

Airway remodeling is characterized by long-term changes of the airway's architecture in asthmatic patients, associated with lung function decline. This process is characterized by the reorganization of the epithelial and subepithelial tissues, which also includes mucus hypersecretion and thickening of the bronchial smooth muscle layer. Increased areas of muscular and submucosal glands are mainly observed in patients with uncontrolled bronchial asthma, despite treatment with high doses of inhaled corticosteroids. Thus, the new therapeutic strategies should be targeted to prevent bronchial wall remodeling in asthmatic patients, by reducing the increase of the bronchial muscle area and limiting the mucus hypersecretion.

CONFLICT OF INTEREST AND FUNDING

GENDER DETERMINATION BY LINEAR MEASUREMENTS OF THE FRONTAL SINUS USING CBCT SCANS (Abstract): This research aimed at identifying gender by performing linear measurements of the frontal sinus (FS) on images obtained from CBCT scans. **Material and methods:** We analyzed 30 CBCT scans from adult patients of Romanian origin aged between 18-65 years old using the Romexis 4.4.0. software (Planmeca, Helsinki, Finland). Several linear measurements were made: maximum height of the right frontal sinus, maximum height of the left frontal sinus, maximum length of the right frontal sinus, maximum length of the left frontal sinus, total length of the frontal sinus, maximum anterior-posterior diameter of the right frontal sinus, maximum anterior-posterior diameter of the left frontal sinus. All data was assessed on 0.200mm slice thickness images in different anatomical planes. **Results:** Based on both measurements of the maximum height of the right FS, 60% of females and 60% of males were correctly identified while the same measurements on the left FS achieved gender estimation accuracy up to 53.3% in females and 40% in males. The assessment of the maximum length of the right FS lead to a correct prediction of up to 53.3% in females and 53.3% in males, while for the maximum length of the left FS, female individuals were properly identified in 53.3% of cases and males in 46.7% of cases. Measuring the total length of the FS allowed us to identify up to 60% of females and 60% of males. Both measurements of the maximum anterior-posterior diameter of the left FS estimated correctly 66.7% females, 73.3% males. **Conclusions:** The best gender predictor variable of the FS is the maximum anterior-posterior diameter, with a correct estimation rate up to 80% in females and 73.3% in males for the right FS. Due to our small and homogenous study group, we recommend further research on a larger and ethnically diverse population. **Keywords:** CBCT, FRONTAL SINUS, GENDER DETERMINATION, LINIAR MEASUREMENTS.

The frontal sinus (FS) is an air-filled, pyramid-like cavity located within the frontal bone. As the other paranasal sinuses (maxillary, sphenoid and ethmoid), the FS is a paired space, lined with a mucous membrane. It serves several functions such as: reducing the weight of the skull, humidifying and regulating air temperature. Each FS develops independently and, oftentimes, one FS is more dominant than the other. Overall, the variability of the FS is well-acknowledged in the literature and its

unique pattern recommends it as an important anatomical area to be analyzed for forensic purposes, particularly for human identification and/or gender determination by using measurements performed on skulls (1), plain X-ray assessments, usually on lateral cephalometric projections (2, 3) and PA views (4, 5) and Caldwell views (6, 7, 8), conventional computed tomography (CT) (9, 10, 11) or cone-beam computed tomography (CBCT) examinations (6, 12, 13, 14).

Current literature did not reach a consensus regarding the age of maximum development of the FS and, because the bone development is completed around the age of 25 years, we chose to limit our study participants to adults only. However, some researchers consider that the FS is a precise indicator of somatic development maturity in children past puberty (15). Previous studies concluded that the FS reaches its maximum dimensions around the age of 20 years old (16) and that its expansion is in direct relation with the masticatory mechanical stress and hormonal levels, highlighting the idea that the FS continues to develop up to 40 years old (17).

Since current data highlights the superiority of the CBCT assessments over extraoral radiographs for forensic purposes (18), we included only 3D images in our study.

This research aimed at identifying gender by performing linear measurements of the FS on images obtained from CBCT scans. The study protocol was approved by the "Grigore T. Popa" UMPH Ethics Committee (reference number: 13084, July 1st, 2015).

The CBCT is a medical imaging device available on the market in Europe since 1996. It allows 3D scanning of the area of interest and uses a reduced radiation dosage and exposure time, rendering superior quality images compared with the conventional computed tomography (CT). Unlike the regular CT, the CBCT uses divergent X-rays, which form a cone. Its' indications include various branches of dental specialties, particularly oral surgery, implantology and orthodontics, being largely used both as a diagnostic and treatment planning exam in every day practice and in research. Due to its' capacity to offer detailed, accurate and reproducible images of the scanned structures, the CBCT has become quite popular in paranasal sinus lesions and forensics.

MATERIAL AND METHODS

We analyzed retrospectively 30 CBCT scans from adult patients of Romanian origin aged between 18-65 years-old. The images were retrieved from a large database of cranial CBCTs which were performed between September 2013 and December 2014 with a Planmeca ProMax 3D Mid (Planmeca, Helsinki, Finland) scanning device. Several linear measurements were made at the inner bony contour of the FSs: maximum height of the right frontal sinus, maximum height of the left frontal sinus, maximum length of the right frontal sinus, maximum length of the left frontal sinus, total length of the frontal sinus, maximum anterior-posterior diameter of the right frontal sinus, maximum anterior-posterior diameter of the left frontal sinus. Due to the software's ability to differentiate between various densities of the structures within the FS area, the sinus mucosa did not interfere with our measurements. All data was assessed on 0.200mm slice thickness images in different anatomical planes. The study included only CBCTs with FSs that did not present any pathology, previous treatments affecting the FS,

artifacts, uni- or bilateral agenesis. The images were exported in DICOM (.dcm) format, introduced into a laptop (Lenovo G50, Lenovo Group Ltd., Beijing, China) and read using the Romexis 4.4.0. software (Planmeca, Helsinki, Finland) by a dentoalveolar surgeon trained in CBCT and an experimented senior radiologist (A.G.B., D.H.), both of which made the measurements (Fig. 1). In the case of interpretation discrepancies, the final analysis was performed by consensus between the researchers. The assessment was repeated following one month from the first measurement.

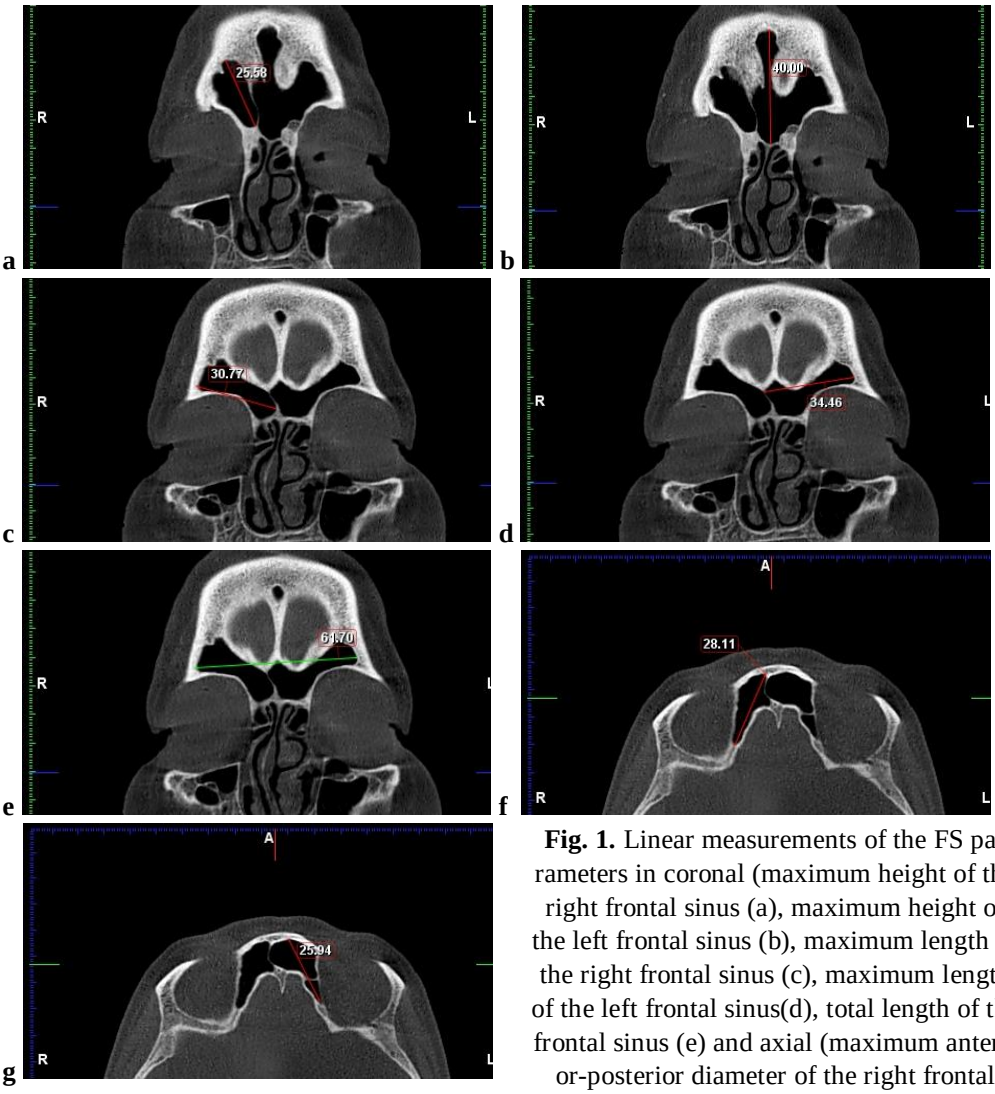

Fig. 1. Linear measurements of the FS parameters in coronal (maximum height of the right frontal sinus (a), maximum height of the left frontal sinus (b), maximum length of the right frontal sinus (c), maximum length of the left frontal sinus(d), total length of the frontal sinus (e) and axial (maximum anterior-posterior diameter of the right frontal sinus (f), maximum anterior-posterior diameter of the left frontal sinus(g) view in a 54 years old female patient.

Statistical Analysis

The statistical analysis was performed using *SPSS 22.0* (SPSS Inc., Chicago, IL, USA). For statistical purposes, the reference value of the signification level was p=0.05, which corresponds to a confidence interval (CI) of 95%. For mean values comparison of the linear characteristics, the Kruskal-Wallis test was performed. The prediction power estimate of the linear characteristics of the FS regarding patients' gender was evaluated using logistic regression. For the accuracy assessment of various parameters used for gender estimation, the kappa coefficient (k) was used. The Landis and Koch reference scale was used for analysis, which allowed us to evaluate the agreement quality as being "poor" (k<0), "fair" (k=0-0.20), "acceptable" (k=0.21-0.40), "moderate" (k=0.41-0.60), "very good" (k=0.61-0.80), and "almost perfect" (k=0.81-1.00).

RESULTS

The first measurement (M1) of the maximum height of the right FS presented significantly higher values ($H_{Kruskal-Wallis}$=5.05, p=0.0245, 95%CI) in male patients (males: $M_{MaxH(M1)}$ - 33.36±8.98SD vs. females: $M_{MaxH(M1)}$ - 27.33±7.6SD) (tab. I).

The calculated value of the area under the ROC curve (AUC=0.6689, p=0.0246, 95%CI: AUC→0.529-0.8081) demonstrates a good prediction rate of the patients' gender based on the first measurement (M1) of the maximum height of the right frontal sinus. Also, the results indicated a 32.8 cut-off value of the first measurement (M1) of the maximum height of the right FS; this threshold offers a good estimation of the patient's gender. The method of gender prediction based on the first measurement (M1) of the maximum height of the right FS presents an 80% sensibility and a 53% specificity (tab. II). Thus, values lower than 32.8 of the first measurement (M1) of the maximum height of the right FS indicate with a high probability that the patient is female. The concordance of the results based on the first measurement (M1) of the maximum height of the right FS was insignificant, the kappa coefficient (k=0.20, p=0.273, 95%CI) indicated a superficial agreement degree (tab. III).

The second measurement (M2) of the maximum height of the right FS presented significantly higher values ($H_{Kruskal-Wallis}$=4.79, p=0.028, 95%CI) in male patients (males: $M_{MaxH(M2)}$ - 33.36±9.05SD vs. females: $M_{MaxH(M2)}$ - 27.48±7.68SD) (tab. I).

The calculated value of the area under the ROC curve for the second measurement (M2) of the maximum height of the right FS being higher than 0.5 (AUC=0.664, p=0.02866, 95%CI: AUC→0.5242-0.8047) confirms a good prediction rate of patients' gender based on the second measurement (M2) of the maximum height of the right FS. The study results indicated a 32.63 cut-off value of the second measurement (M2) of the maximum height of the right FS, which is a reference value for the estimation of patients' gender. An 80% sensibility and a 53% specificity corresponds to this value. Thus, values lower than 32.63 of the second measurement (M2) of the maximum height of the right FS indicate with a high probability the fact that the patient is female (tab. II). Based on the second measurement of the maximum height of the right FS, 60% of female patients and 60% of male patients were correctly predicted. However, the concordance of the results was insignificant, the kappa coefficient (k), (k=0.20, p=0.273, 95%CI) indicated a su-

perficial agreement degree (tab. III).

The first measurement (M1) of the anterior-posterior maximum diameter of the right FS presents significantly higher values ($H_{Kruskal-Wallis}$=9.28, p=0.0023, 95%CI) in male patients (males: $M_{AP\ Max\ Ø\ (M1)}$ - 25.12±5.19SD vs. females: $M_{AP\ Max\ Ø\ (M1)}$ - 21.2±5.45SD) (tab. I).

Left FS AP Max Ø (M1)	25.76±3.73	21.82±5.03	H_{KW}=10.208, p=0.0014*
Left FS AP Max Ø (M2)	25.85±3.96	21.78±4.99	H_{KW}=10.211, p=0.0014

† Values were expressed as number (%) mean ± SD or percent at%; (*) Marked effects are significant at p < .05000
‡ Kruskal-Wallis; Chi-square test or Fisher's exact test.

The insignificant calculated value of the area under the ROC curve (AUC=0.728, p=0.0023, 95%CI: AUC→0.597-0.860) demonstrates a good power of prediction of the values for the first measurement (M1) of the anterior-posterior maximum diameter of the right FS regarding patients' gender. Also, the minimum AUC value calculated in this case (0.597) is higher than the reference value (0.5), which confirms the power of the prediction method. The study results indicated a 23.36 cut-off value of the first measurement (M1) of the maximum diameter of the right FS regarding gender estimation, which corresponds to a 80% sensibility and 66.7% specificity. These results confirm the discriminatory power of the first measurement (M1) of the values for the maximum diameter of the right FS regarding patients' gender. Values higher than 23.4 accurately estimate that the patients are males (tab. II). Based on the first measurement (M1) of the maximum diameter of the FS, 80% females and 66.7% males were correctly predicted. The concordance of the results was significant, the kappa coefficient (k=0.467, p=0.01, 95%CI) indicated a moderate degree of agreement (tab. III).

TABLE II.

Sensitivity, Specificity, cut-off value for the linear characteristics of the FS regarding patients' gender prediction

Frontal sinus. Anatomical particularities	Sensitivity	Specificity	Cut off value	p-value (95%CI)
Right FS Max H (M1)	0.8000	0.5333	32.77	.02463*
Right FS Max H (M2)	0.8000	0.5333	32.63	.02866*

Right FS AP Max Ø (M2)	66.7%	80%	**0.467**	0.010*
Left FS AP Max Ø (M1)	73.3%	66.7%	**0.410**	0.028*
Left FS AP Max Ø (M2)	73.3%	66.7%	**0.450**	0.028*
Statistical test - 95%CI (Confidence Interval) - (*) Marked effects are significant at p < .05000				

The second measurement (M2) of the maximum anterior-posterior diameter of the right FS presented significantly higher values ($H_{Kruskal-Wallis}$=7.89, p=0.005, 95%CI) in males (males: $M_{AP\ Max\ Ø\ (M2)}$ - 25.19±5.37SD vs. females: $M_{AP\ Max\ Ø\ (M2)}$ - 21.16±5.35SD) (tab. I). The insignificant calculated value of the area under the ROC curve (AUC=0.711, p=0.0049, 95%CI: AUC→0.576-0.845) demonstrates a good prediction rate of the values of the second measurement (M2) of the of the maximum anterior-posterior diameter of the right FS regarding patient's gender. Also, the minimum value of the calculated AUC in this case is significant (0.576); this confirms our conclusion.

The results of the study indicated a cut-off value of the second measurement (M2) of the maximum diameter of the right FS of 23.15 for gender prediction, which has a corresponding sensibility of 80% and specificity of 66.7%. The prediction power of this parameter regarding the patient's gender is high (tab. II). Based on the second measurement (M2) of the maximum diameter of the right FS, 80% of females and 66.7% of males were correctly predicted. The concordance of the results was significant, the kappa coefficient (k=0.467, p=0.01, 95%CI) indicated a moderate agreement degree (tab. III).

DISCUSSION

Due to the ability of CBCT devices to generate 3D reconstructions of the scanned structures, most research in this field focuses on volumetric measurements. However, linear measurements performed on CBCT images with the aim of gender estimation have been successfully completed in the past. In a previous study performed on CBCT scans from 77 Romanian patients, up to 92% females were correctly identified by using the frontal sinus index (6).

A study performed on 200 Persian patients (100 females, 100 males) using conventional computed tomography (CT) scans that analyzed various linear measurements of the FSs and other characteristics including pneumatizing and septa concluded that best gender predictor was the maximum height of the left FS (61.3%) (9). However, these researchers consider that the FS parameters should be used for gender determination as part of a comprehensive evaluation that should include other factors. These results are in accordance with other publications (19, 20, 21). Our study found a low prediction capacity of the maximum height of the left FS (40% in males and a maximum of 53.3% in females).

In a multi-detector, computed tomography (MDCT) study conducted on 100 patients (50 females and 50 males), the anterior-posterior length of the FS was the best predictor for gender with an accuracy of 67% (70% for females and 64% for males (22). Our research shows that the best gender estimator was also the maximum anterior-posterior diameter of the FS in all CBCT view. Based on the first measurement (M1) of the maximum diameter of the FS, 80% of female patients and 66.7% of male patients were correctly identified. The concordance of the results was significant; the kappa coefficient (k=0.467, p=0.01, 95% CI) indicated a moderate agreement degree. Based on the second measurement (M2) of the maximum diameter of the FS, 80% of female individuals and 60 % of male individuals were correctly predicted. The concordance of the predicted results based on the actual measurements was significant, the kappa coefficient (k=0.46, p=0.01, 95%CI) indicated a moderate degree of agreement. Using the first measurement (M1) of the

maximum diameter of the left FS, 66.7% of females and 73.3% of males were correctly identified. The concordance of the predicted results based on the actual measurements was significant, the kappa coefficient (k=0.41, p=0.028, 95% CI) indicated a moderate agreement degree. Considering the maximum diameter of the left frontal sinus (M2), 66.7% of females and 73.3% of male individuals were correctly assessed. The concordance of the results was significant, the kappa coefficient (k=0.45, p=0.028, 95% CI) indicated a moderate agreement degree.

CONCLUSIONS

The best gender predictor variable of the FS is the maximum anterior-posterior diameter in the all CBCT view, with a correct estimation rate up to 80% in females and 73.3% in males for the right FS.

Due to our small and homogenous CBCT study group, we recommend further research on a larger and ethnically diverse population, including children past puberty. We also recommend the quantification of unilateral and bilateral agenesis of the frontal sinus in the Romanian population.

NEWS

THE ANTI-CARCINOGENIC ROLE OF NICOTINAMIDE

Nicotinamide is an amide form of vitamin B3 that has the potential to treat dermatological conditions such as rosacea, acne, or atopic dermatitis. According to Nazarali *et al.*, nicotinamide has anti-carcinogenic properties and can be used in topical or oral forms as a chemo preventive agent against skin cancer. This can be explained by its ability to enhance DNA repair and prevent the immunosuppression induced by UV light. It is also a precursor of key coenzymes such as nicotinamide adenine dinucleotide, used in the synthesis of adenosine triphosphate (ATP). The author concludes that nicotinamide plays an important role in energy-dependent cellular processes such as DNA repair. (Nazarali S, Kuzel P. Vitamin B Derivative (Nicotinamide) Appears to Reduce Skin Cancer Risk. *Skin Therapy Lett*. 2017 Sep; 22(5): 1-4.)

INDICATORS OF PROGNOSIS IN COMMUNITY-ACQUIRED BACTERIAL MENINGITIS (Abstract) Bacterial meningitis is a medical, neurological and sometimes neurosurgical emergency, being an important cause of morbidity and mortality worldwide. Aim: Analysis of some epidemiological parameters with possible role in prognosis prediction, and analysis of therapeutic conduct in relation with clinical evolution. **Material and methods**: Retrospective study of the medical records of 70 patients with a discharge diagnosis of bacterial meningitis. The patients were admitted to the Iasi Infectious Diseases Hospital in 2014 and 2015. **Results**: A larger number of patients under 50 years of age exhibited the symptomatic associations (fever, headache, stiff neck) compared to those aged over 50 years ($p < 0.05$). Discordance between diagnoses, found in 65.71% of patients correlates with adverse events and death ($p = 0.037$). A larger proportion of patients on modified therapy (46.67%) died as compared to those in whom treatment was not changed (22.50%) ($p = 0.033$). We found that a CSF glucose level under 0.4 g/L is more frequently associated with coma ($p = 0.002$). Statistically significant associations were found between CSF glucose level <0.7 g/L and the following clinical signs and symptoms: fever, headache and neck stiffness ($p = 0.043$). Patients with pathological changes found at CT examination were more likely to have an unfavorable outcome ($p = 0.014$). **Conclusions**: The high rates of comorbidities, the presence of coma and abnormal CT findings on admission, as well as the discordant admission and discharge diagnoses may be considered factors of negative prognosis. **Keywords**: BACTERIAL MENINGITIS, PROGNOSIS FACTORS, DIAGNOSIS.

Bacterial meningitis is a medical, neurological, and sometimes neurosurgical emergency being an important cause of morbidity and mortality worldwide. It is estimated that the mortality rate of bacterial meningitis ranges from 7% to 30% in the developed countries, and reaches even 50% in the developing world. Neurological sequels such as hearing loss and psychomotor disorders are reported in almost half of the survivors. The importance of the problem is evidenced not only by the large number of days of medical care for survivors, but also for rehabilitation (1, 2).

Statistical data underline the importance of the correct therapeutic management of

the patient suspected of or diagnosed with bacterial meningitis. In these circumstances, the initial assessment of the patient and the evaluation of prognostic factors are essential. Given the high risk of sequels and even death, identifying the elements with prognostic role as immediately after the diagnosis was made may decrease the risk of adverse events.

The objectives of our study are: analysis of some epidemiological parameters (age, gender, personal medical history) with possible role in prognosis prediction, be it favorable or unfavorable, in a group of patients with bacterial meningitis confirmed by clinical and laboratory findings, and analysis of therapeutic management (appropriate/inappropriate, early/late) in the patients in which a complete cure was obtained, compared to those who developed complications/sequelae or died.

MATERIAL AND METHODS

Our study retrospectively reviewed the medical records of 70 patients consecutively admitted and treated for bacterial meningitis to the Iasi "Sfânta Parascheva" Infectious Diseases Hospital during the period 2014-2015. Cases of posttraumatic meningitis, postoperative bacterial meningitis, or ventriculo-peritoneal shunt (VPS)-associated meningitis were excluded from the study. The diagnosis of meningitis was based on clinical criteria (fever, headache and neck stiffness, disorders of consciousness) and cerebrospinal fluid (CSF) criteria (leukocytosis >10/mm^3, ± increased and decreased CSG glucose levels, positive cultures or direct exams). No written consent was given by the participants, as data were collected and analyzed anonymously. The data were statistically analyzed using Epi Info and the used parametric test was the two-tailed test.

RESULTS

For comparative analysis by age group, we decided to divide the 70 patients into two groups: patients aged less than or equal to 50 years (36 cases, 51.42%), and patients aged over 50 years (34 cases, 48.57%). As one can see in Table I, a larger number of patients under 50 years of age exhibited the described symptomatic associations as compared to those aged over 50 years.

TABLE I

Age-correlated clinical manifestations

Signs and symptoms	>50 years of age No (%)=34	<50 years of age No (%)=36	*p*
Fever, headache, stiff neck	10 (29%)	23 (63.8%)	0.003
Headache, stiff neck	13 (38.24)	26 (72.22)	0.004
Fever, headache	19 (55.88)	31 (86.11)	0.005
Fever, stiff neck	13 (38.24)	25 (69.44)	0.008
Fever, headache, vomiting	8 (23.53)	18 (50.00)	0.021

Although there are significant percentage differences between the two groups in the following reported parameters: hospital stay over 14 days (p = 0.816), evolution towards death (p = 0.149), coma (p = 0.136), other neurological disorders (p = 0.871), CSF albumin levels over 3 g/L (p = 0.879) or CSF glucose levels under 0.7 g/L (p = 0.065), no statistically significant correlations have been found. Decreased CSF glucose levels were more frequently found in patients < 50 years of age (tab. II).

Discordance between initial and final diagnosis, found in 65.71% of patients (46 patients), correlated with adverse events and death (p = 0.037), correlation that may be probably due to the inappropriate management. A number of 19 deaths (41.30%) were recorded in the group in which diagnoses did not coincide, as compared to 4 deaths (16.67%) in the group with concordance between diagnoses (tab. III).

TABLE II

Biological parameters and case evolution according to age category

Parameters	> 50 years of age No (%)=34	<50 years of age No (%)=36	*p*
CSF albumin > 3 g/L	10 (29.41)	10 (27.78)	0.879
CSF glucose <0.7 g/L	23 (38.65)	31 (86.11)	0.065
Coma	12 (35.29)	7 (19.44)	0.136
Other neurological disorders	23 (67.65)	25 (69.44)	0.871
Hospitalization for >14 days	17 (50.00)	19 (52.78)	0.816
Evolution towards death	14 (41.18)	9 (25.00)	0.149

TABLE III

Clinical course and therapy reshuffling reported to the concordance between diagnosis upon admission and diagnosis at discharge

Parameters	Discordance No (%)=46	Concordance No (%)=24	*p*
Deaths	19 (41.30%)	4 (16.67%)	0.037
Cured	27 (58.70%)	20 (83.33%)	
Therapy reshuffling	23 (50.00)	7 (29.17)	0.094

No statistically significant correlations could be established between diagnostic concordance and treatment reshuffling (p = 0.094), although there were percentage differences between the two groups in terms of the above-mentioned parameters (tab. III). A statistically significant association was that between the less-than-2-day-period to admission (and treatment) and a CSF albumin level of over 3 g/L (p = 0.033) (tab. IV).

Of the 20 patients in which CSF albumin level was greater than 3 g/L, 35.71% were hospitalized and received treatment in less than two days (tab. IV). This could be explained by the existence of a rapid and more pronounced inflammatory reaction at the CSF level.

TABLE IV

Mortality rate was similar in the two groups differentiated through the onset-to-hospitalization time

	Treatment at <48 hours No (%)=25	Treatment at >48hours No (%)= 45	*p*
CSF albumin >3g/L	11 (44.00)	9 (20.00%)	0.033
Death	8 (32%)	15 (33.33%)	0.909

Therapy reshuffling also influenced the clinical course: a larger proportion of patients receiving modified therapy (46.67%) died as compared to those in which treatment was not changed (22.50%) (p = 0.033; OR = 3.013) (tab. V).

TABLE V

Associations between treatment reshuffling and evolving features

Parameters	Reshuffling No (%)=30	Without reshuffling No (%)=40	*p*
Hospital stay >14 days	20 (66.67%)	16 (40%)	0.027
Death	14 (46.67%)	9 (22.50%	0.033
Coma present	9 (30%)	10 (25%)	0.641
CSF albumin >3g/L	7 (23.33%)	13 (32.50%)	0.400
CSF glucose <0.7 g/L	21 (70%)	32 (80%)	0.334
Neurological disorders	22 (73.33%)	26 (65%)	0.457

One can notice that in most cases therapy reshuffling was required when symptoms on admission persisted or worsened. In descending order of frequency, the reasons were: the results of antibiotic sensitivity tests and the persistence or worsening of symptoms present on admission or overlap of disorders of consciousness occurring during hospital stay. Of the 70 patients, 21 (30%) have received antibiotic therapy prior to their admission to the Infectious Disease Clinic (tab. VI).

TABLE VI

Clinical manifestations associated with prior antibiotic therapy

Parameters	No Prior AB treatment No (%)=49	Prior AB treatment No (%)=21	*p*
Fever, headache and disorders of consciousness	7 (14.29%)	3 (14.29%)	1
Headache and disorders of consciousness	9 (18.37%)	5 (23.81%)	0.601
CSF elements >1,000/mm³ (Nr=21)	13 (26.53%)	8 (38.10%)	0.333

In addition, all patients in the group with elevated white blood cell counts were more prone to exhibit disorders of consciousness (coma) (p = 0.0008; OR = 2.162). In 89.47% of coma cases, WBC count was over 11,000/mm^2. Thus, it is the systemic inflammatory response that has been statistically correlated with an unfavorable course (tab. VII).

We have found that CSF glucose level below 0.7 g/L was more frequently associated with coma than a normal or an increased level (p = 0.002; OR = 6.98), 52.63 % of the patients with CSF glucose below 0.7 g/L presenting disorder of consciousness. Neck stiffness was also correlated with CSF glucose below 0.7 g/L (p = 0.006). Forty of the 54 patients with CSG glucose below 0.7 g/L (74.07%) and only 6 of the 16 patients with CSF glucose over 0.7 g/L (37.50 %) have experienced this symptom (tab. VIII).

Statistically significant associations were established between CSF glucose

level <0.7 g/L and the following clinical signs and associations of signs and symptoms: neck stiffness (p = 0.006), fever and neck stiffness (p = 0.035), fever, headache and neck stiffness (p = 0.043), headache and neck stiffness (p = 0.024).

TABLE VII

Clinical and biological manifestations related to serum white blood cell count

Parameters	WBC > 11,000/mm³ No (%)=40	WBC <11,000/mm³ No (%)=30	*p*
Fever	38 (95%)	21 (70%)	0.004
Fever, headache	29 (72.50%)	21 (70.00%)	0.818
Coma (n=19)	17 (42.50 %)	2 (6.67%)	0.0008
Death (n=23)	20 (50%)	3 (10%)	0.0004
CSF elements> 1,000/mm³ (21)	16 (35%)	5 (13.33%)	0.040
ESR > 50 mm/h	17 (42.5%)	9 (30%)	0.284

TABLE VIII

Clinical manifestations and death rate related to the initial CSF glucose level

	CSF glucose <0.7 g/L No (%)=54	CSG glucose > 0.7 g/L No (%)=16	*p*
Coma	10 (18.52)	9 (56.25)	0.002
Neck stiffness	40 (74.07)	6 (37.50)	0.006
Fever, neck stiffness	33 (61.11)	5 (31.25)	0.035
Fever, headache, neck stiffness	29 (53.79)	4 (25.00)	0.043
Headache, neck stiffness	34 (62.96)	5 (31.25)	0.024
Other neurological disorders	37 (68.52)	11 (68.75)	0.986
Death	15 (27.78)	8 (50.00)	0.096

No statistically significant associations have been found between CSF glucose level and progression to death (p = 0.096) or neurological disorders, other than those of consciousness (p = 0.986) (tab. VIII). In the patients who underwent blood cultures, 39 were negative and only 10 were positive *for S. aureus* (8 cases), *Salmonella enterica* (1 case), Streptococcus Group D (1 case).

Of the 70 patients, 23 (30%) had positive CSF cultures for: *S. aureus* (8 cases), *N. meningitidis* (4 cases), *Listeria monocytogenes* (3 cases), *Streptococcus pneumoniae* (3 cases), *Streptococcus Group D* (2 cases), *Salmonella enterica* (1 case), coagulase-negative Staphylococcus (1 case), and alpha hemolytic Streptococcus (1 case). All 8 cases of *S. aureus* meningitis had positive blood cultures which proved the hematogenous spread of the pathogen from a primary site. Positive results were obtained in 23.40% of survivors, while the microbial agent was isolated in 52.17% of the deceased patients.

A greater number of patients with negative CSF cultures presented low CSF glucose and elevated CSF albumin level over 3 g/L, but the differences were not statistically significant (tab. IX).

Patients with pathological changes detected at CT examination or associated comorbidities were more likely to have an unfavorable course by contrast with those with normal CT scans (p = 0.014) or no associated comorbidities, respectively (tab. X, tab. XI).

TABLE IX

Frequency of CSF culture positivation related to clinical manifestations and biological parameters

Parameters	Positive CSF cultures No (%)=23	Negative CSF cultures No (%)=47	*p*
CSF albumin > 3 g/L	7 (30.43%)	13 (27.66%)	0.809
CSF glucose < 0.7 g/L	16 (69.57 %)	38 (80.85%)	0.401
Previous treatment	7 (30.43%)	20 (42.55%)	0.327
Coma	9 (39.13%)	10 (21.28%)	0.114
Other neurological disorders	14 (60.87%)	34 (72.43%)	0.331

TABLE X

CT appearance related to CSF albumin level and correlated with unfavorable outcome

Parameters	Pathologic CT exam No (%)=28	Normal CT exam No (%)=20	*p*
Death	17 (60.71%)	5 (25.00%)	0.014
CSF albumin >3 g/L	3 (10.71%)	10 (50.00%)	
CSF albumin <3 g/L	25 (89.29%)	10 (50.00%)	0.002

TABLE XI

Associations between comorbidities and clinical course and imaging manifestations

Parameters	Comorbidities and APP No (%)=54	No comorbidities and APP No (%)=16	*p*
Fever, headache, neck stiffness	22 (40.74%)	11 (68.75%)	0.048
Oher neurological disorders	37 (68.52%)	11 (68.75%)	0.986
Death	20 (37.04%)	3 (18.75%)	0.171
Pathological CT exam	25 (46.30%)	3 (18.79%)	0.048
Coma	14 (31.82%)	5 (31.25%)	0.966

DISCUSSION

Data from the literature underline that clinical manifestations of bacterial meningitis are rather blurred or unusual in patients over 50 years of age. This has also been observed in our patient group which showed significant differences regarding the presence of age-group specific symptoms of meningitis. Similar results have been reported by van de Beek (3), 44% of the cases presenting the fever-neck stiffness-impaired consciousness triad, which could not be associated with a higher mortality rate.

Lucena et al. (4) reported that fever, neck stiffness and vomiting were present in most patients, and their absence was associated with adverse prognosis. Domingo et al. reported that 50% of the elderly patients presented the meningeal triad compared with 8% of the younger patients (5).

Another negative prognostic factor is hospitalization in the context of disorders of consciousness (6, 7, 8). Mendizabala et al. in their study (9) showed that the absence of headache and vomiting was directly associated with a greater risk of death, as the lack of suggestive signs may delay

diagnosis and treatment initiation. In our study an altered level of consciousness was more frequently found in patients aged over 50 years, and the data obtained by us are like those reported by other authors which report disorders of consciousness in 68% of the patients over 65 years of age(5, 10, 11).

The current study does not report significant differences in the prognosis of patients in whom treatment was initiated within more than 48 hours compared to less than 48 hours of symptom onset, but this could be accounted for by the heterogeneity of the compared groups in terms of symptom severity, age group and etiology, requiring a more detailed statistical analysis on a larger number of cases. Similarly, Mendizabala et al. (9) found no statistical association between the progression to death and the time elapsed between symptom onset and hospital admission. Contrary, Aronin et al. (12) argue that the delay in administering treatment worsens prognosis. The results of the study may be explained by the initiation of appropriate antimicrobial therapy without delay and low incidence of resistant bacterial strains.

We observed changes in the spectrum of acute bacterial meningitis compared with a study performed in the same hospital between 2000 and 2009 (13). *Staphylococcus aureus* was the predominant cause in this 1-year study while *S. pneumoniae* was the most common pathogenic agent of adult meningitis over the 10-year period. We also found a lower rate of positive CSF cultures (30% *vs.* 51%), although 30% of the patients enrolled in both Romanian studies had benefited from pre-admission antibiotic therapy (13).

The present study, as other references in the literature, demonstrates that the isolation of the causative agent from biological fluids (blood or CSF) is associated with an adverse prognosis. Mendizabala et al. (9) showed that positivation of blood cultures increases the risk of death, with 49.1% of cases presenting positive cultures compared to 19.5% in the control group. Also, McMillan et al. (14) showed that death is more likely to occur in patients with positive blood cultures and lower CSF cellularity (<1,000 elements). Moreover, van de Beek (3) asserts that the risk of death increases 6 times with the isolation of the causative agent.

Analysis of biochemical data from CSF suggested that a CSF glucose level below 0.7 g/L accompanied in a greater proportion a more severe clinical presentation, even severe, marked by coma. This low level could be correlated with the progression to death. The same finding is reported by McMillan et al. (14) in their study. However, Mendizabala et al. (9) claim that CSF glucose does not influence the prognosis of the patients.

Among the limitations of the study we mention the small number of patients investigated during only one year of study and the absence of the comparison between clinical and biological parameters based on etiology, due to the small number of patients with positive CSF cultures.

CONCLUSIONS

Our study shows that the high rates of comorbidities, the presence of coma and pathologic CT exam on admission, as well as the discordant admission and discharge diagnoses may be considered negative prognostic factors. At the same time, we underline the importance of symptomatology which depends on patient's age. The present study demonstrates that the isolation of the causative agent from biological

fluids (blood or CSF) is associated with a negative prognosis. Another important result of our study was that CSF glucose below 0.7 g/L accompanied by a severe clinical presentation could be correlated with progression to death. It is very important to recognize different aspects of meningitis for good clinical practice and prognosis. We believe that our study is a good tool for achieving this goal.

SEVERITY OF DUODENAL HISTOLOGY AND TISSUE TRANSGLUTAMINASE ANTIBODY LEVELS CORRELATE WELL IN ADULT CELIAC DISEASE IRRESPECTIVE OF CLINICAL FEATURES (Abstract): Celiac disease (CD) is a chronic immune-mediated enteropathy that occurs in genetically predisposed individuals. The clinical phenotypes range from classical gastrointestinal manifestations to only atypical signs, thus being a challenge to diagnose. **Aim:** To investigate the relationship between duodenal histology, specific antibody levels and clinical presentation in adult Romanian CD patients. **Material and methods**: Study design: retrospective retrieval of information prospectively entered into a structured database including 81 adult patients diagnosed with CD admitted with symptoms of abdominal disturbances (diarrhea, heartburn, nausea, vomiting, regurgitation, abdominal pain) to the Iasi Institute of Gastroenterology and Hepatology, "Sf. Spiridon" Emergency Clinical County Hospital between January 2012 and December 2016. The demographic, clinical, serological, and histological characteristics of individuals with CD were reviewed. **Results:** The female: male ratio was 3:1, 60 (71.1%) female patients, mean age 40.02±12.14 years. A total of 48.1% patients presented with gastrointestinal (GI) complaints and 51.9% presented mostly with non-GI manifestations, with a slightly more advanced age at symptom onset in the latter (38 yrs. *vs.* 47 yrs.). Marsh-Oberhuber classification was used to assess mucosal injury and Marsh 3c lesions were found in 25 (30.9%) cases. When assessing the serological parameters, IgA anti-tissue transglutaminase (IgA-tTG) antibody (61.45±76.458 u/mL *vs.*162.02±106.179 u/mL, p=0.001) and IgA anti-gliadin antibody (IgA-AGA) levels (61.83±69.41u/mL *vs.* 77.15±71.02 u/mL, p=0.001) correlated with intestinal villous atrophy (Marsh 3a and 3c) in CD patients by Spearman rank correlation. Of the symptoms, abdominal distention and diarrhea were associated with abnormal histology. Hemoglobin levels were determined and anemia was diagnosed in 61.7% of the patients with elevated IgA-tTG levels (r= -0.316; p=0.004), IgA-AGA (r= -0.301; p=0.006) and Marsh 3b-3c lesions (p=0.0048). Of the biological markers included in the statistical analysis, low iron levels (cut off 30 mg/dl), hypocholesterolemia and low protein levels were associated with Marsh 3b lesions (p=0.006) and elevated tTG-IgA levels (r= -0.384; p=0.001). **Conclusions**: IgA-tTG and AGA levels correlate with duodenal villous atrophy in adult CD patients. An IgA-tTG level >160 was nearly always associated with severe CD histopathology. GI and non-GI symptoms are not reliable predictors of CD. **Keywords:** CELIAC DISEASE, MARSH CLASSIFICATION, CLINICAL MANIFSTATIONS, ANTI-TISSUE TRANSGLUTAMINASE.

Celiac disease (CD) is a chronic immune-mediated enteropathy that occurs in genetically predisposed individuals (1, 2) and the most frequent food intolerance with an increasing prevalence over the last three decades (3). This has been partially prompted by globalization, which led to an increased consumption of gluten-containing food worldwide. The development of new sensitive and specific serological tests and their extended availability, as well as the best knowledge of the disease including a wide clinical spectrum have greatly facilitated CD diagnosis, being indirectly responsible for the rising prevalence (4). In Europe, a recently published large international, multicenter study investigating a wide population sample revealed an overall prevalence of 1% (5).

Unfortunately, no one test for CD has a perfect sensitivity or specificity. The clinical phenotypes range from classical gastrointestinal manifestations to only atypical signs, thus making the clinical diagnosis a challenge (6-8). As a rule, CD diagnosis can be made by serological tests, searching for ant tissue transglutaminase (tTG) and anti-endomysium (EMA) auto-antibodies, but confirmation of intestinal damage relies on small bowel biopsy and histological analysis, mainly in Europe (9). Nonetheless, the prevalence of seronegative CD is 6-22% of all diagnosed cases (10), the histological abnormalities associated with CD can be patchy (11,12), and a normal endoscopic appearance of the duodenum may occur in the presence of villous atrophy (13-16). The aim of the study was to investigate the relationship between duodenal histology, specific antibody levels and clinical presentation in adult CD Romanian patients.

MATERIAL AND METHODS

The study design included a retrospective retrieval of information prospectively entered into a structured database carried out at the Iasi Institute of Gastroenterology and Hepatology, which serves as a tertiary care referral center. The study was conducted between January 2012 and December 2016 and included 81 adult CD patients. In all CD cases, the diagnosis was established by a combination of positive IgA-tTG, IgA-AGA and biopsy results. Abdominal pain, diarrhea, constipation, bloating, nausea and vomiting were considered GI manifestations, and enclosed fatigue, joint pain, irritability, anorexia, anemia, aphthous stomatitis, short stature non-GI manifestations.

After obtaining a written informed consent, all subjects underwent upper endoscopy during which duodenal biopsies were obtained. The final Marsh score for each patient was graded according to the most affected site (highest Marsh score). The biopsies were evaluated by a single experienced pathologist blinded to all clinical data. The mucosal specimens were graded independently according to the Marsh-Oberhuber classification as follows: Marsh 0 denotes normal villi and crypt depth with no excess of intraepithelial lymphocytes (IEL), Marsh 1-2 denotes normal villi but intraepithelial lymphocytosis without (1) or with (2) hyperplastic crypts, and Marsh 3a-c denotes varying degrees of villous atrophy with hyperplastic crypts (17). Multiple biopsies (minimum of three) were taken during upper endoscopy from the bulb and distal duodenum. Immunohistochemical studies were performed using anti-CD3 antibody and an IELs count was noted (lymphocytosis >25/100 enterocytes).

Quantative analysis was performed us-

ing ELISA technique. IgA and IgG-tTG were reported according to the manufacturer's cut off as UI/mL and classified as negative <8 IU/mL and positive ≥8 IU/mL. Serum samples containing more than 12 U/mL were considered positive for tTG and for AGA, respectively, as recommended by the manufacturer. Total IgA serum levels were measured. A serum IgA concentration below 0.07g/dl was graded as IgA deficiency by an immunoturbidimetric assay. Detailed information regarding demographics, symptoms at presentation, duration, type of investigations performed, type of treatment including gluten-free diet were recorded.

Statistical analysis was performed using *SPSS 18.0* (*SPSS Chicago Inc., IL, USA*). Continuous data were expressed as mean ± SD and categorical data as percentage. A P-value less than 0.05 was considered statistically significant. The study was approved by the ethical committee and all participants were informed about the study according to the study protocol and gave their written informed consent.

RESULTS

A total of 81 patients met the inclusion criteria of the study with a female to male ratio of 3:1, with a majority of 60 (71.1%) female patients, mean age 40.02±12.14 years (fig.1). The baseline characteristics of the participants are shown in Table I. Family history of CD was identified in 12 (14.8%) cases. The proportion of newly diagnosed CD patients was high: 68 (84%), 48 female patients (70.6%), mean age 40.09±12.67. The prevalence of associated diseases was low, 7 (8.6%), 3 (3.7%) cases being diagnosed with thyroid disease and 4 (4.9%) cases with chronic idiopathic hypertransaminasemia.

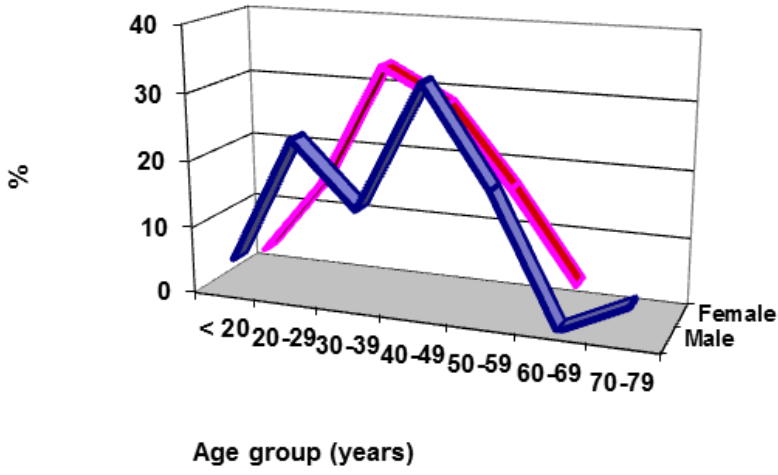

Fig. 1. Prevalence of CD by age and gender

A total of 39 (48.1%) patients presented with GI complaints and 42 (51.9%) of patients presented mostly with non-GI manifestations, with a slightly more advanced age at symptom onset in in the latter (38 yrs. *vs.* 47 yrs.). Interestingly, GI symptoms were more common in patients with lower IgA-tTG <100U/mL

levels, 21 (26.9%), compared to patients with levels >100 U/mL, p=0.007. Marsh-Oberhuber classification was used to assess mucosal injury and varying degrees of villous atrophy were identified in 59 (72.8%) cases as follows: complete atrophy lesions (Marsh 3c) in 25 (30.9%) cases, Marsh 3a in 24 (29.6%), Marsh 3b in 10 (12.3%), and Marsh 1,2 in 22 (27.1%) cases. The severity of duodenal lesions was not influenced by patients' age (F=1.691; df=3; p=0.176).

TABLE 1
Characteristics of celiac disease patients

Patient characteristics	n (%)
Age, median (range), yrs.	38(18-72)
Females, n, (%)	60 (71.1%)
Gastrointestinal symptoms, n, (%)	39(48.1%)
Extra intestinal symptoms, n, (%)	42(51.9%)
Family history of CD, n, (%)	12 (14. 8%)
Newly diagnosed patients, n, (%)	68(84%)
Patients on a gluten free diet, n, (%)	10(12.3%)
CD associated comorbidity*, n, (%)	7(8.6%)

*thyroid disease, dermatitis herpetiformis, ataxia, type 1 diabetes, autoimmune liver disease, unexplained hypertransaminasemia, selective IgA deficiency.

When assessing the serological parameters, IgA-tTG antibody levels (61.45± 76.458 u/mL *vs.* 16.02±106.179 u/mL, p=0.001) and IgA-AGA antibody levels (61.83±69.41u/mL *vs.* 77.15±71.02 u/mL, p=0.001) correlated with intestinal villous atrophy (Marsh 3a and 3c) in CD patients by Spearman rank correlation (fig.2). Mild enteropathy (Marsh 1, 2) was identified in 22 (27.1%) cases with mean tTG levels of 32.44 ± 37.994 U/mL. Strongly positive antibody levels (IgA-tTG>160 units) were highly specific (>97%) for Marsh 3c lesions. Of the GI symptoms anemia, nausea and diarrhea were associated with abnormal histology (Marsh 3a-c lesions) when compared to mild duodenal lesions (Marsh 1, 2). The prevalence of non-GI manifestations was similar and was not influenced by the severity of mucosal lesions. Nevertheless, patients with villous atrophy presented more often with anemia compared with patients with mild enteropathy (p=0.048).

Hemoglobin, ferritin, iron, vitamin B12, albumin, folate, calcium and total protein levels were measured. When assessing the hematological parameters, hemoglobin levels were determined and anemia was diagnosed in 61.7% patients with Marsh 3b and 3c histological lesions (p=0.0048), elevated IgA-tTG levels (r=-0,316; p=0.004) and IgA-AGA (r=-0,301; p=0.006). Of the biological markers included in the statistical analysis, low iron levels (cut off 30 mg/dL), hypocholesterolemia and low protein levels were associated with Marsh 3b lesions (p=0.006) and elevated IgA-tTG levels (r=-0,384; p=0.001). The lowest mean iron levels were found among patients with subtotal and total villous atrophy, p=0,004.

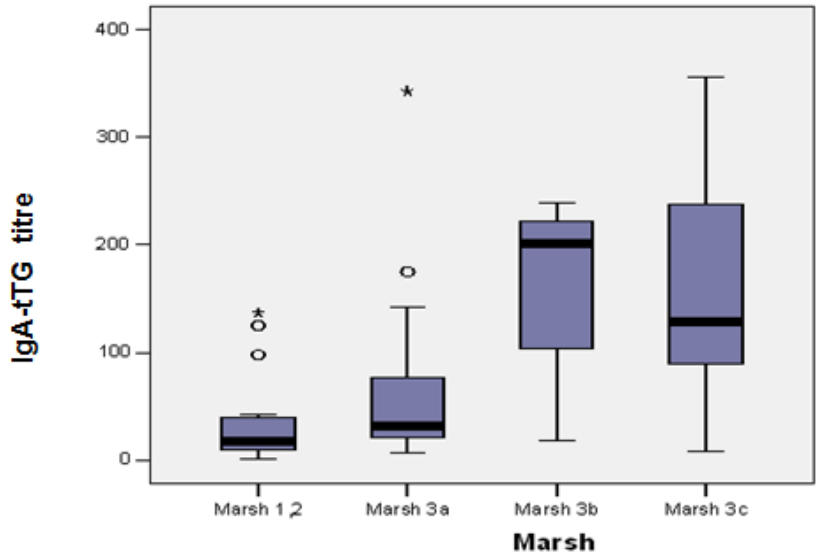

Fig. 2. Correlation between IgA-tTG level and severity of mucosal damage according to Marsh-Oberhuber classification.

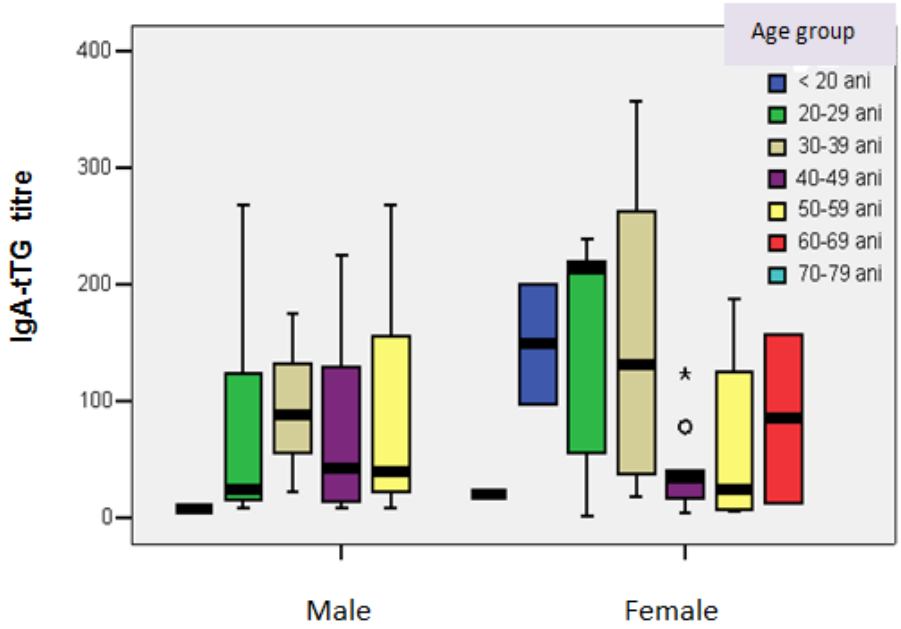

Fig. 3. Gender and age-group distribution of IgA-tTG level

DISCUSSION

Gastrointestinal symptoms alone cannot accurately differentiate CD from other common gastrointestinal disorders (20-50% of patients with CD met the Rome criteria for irritable bowel syndrome) (18,19). Whilst current literature suggests a discriminatory role for a high-risk group (anemia, weight loss, diarrhea, dermatitis herpetiformis) our data suggest that no single clinical feature is a reliable predictor or risk stratifier for CD and the disease occurs irrespective of clinical presentation (20,21). According to our results, CD is more frequent among young female patients, with a shift in clinical pattern occurrence towards atypical presentation in older patients, which is associated with misdiagnosis and delayed diagnosis.

The results showed significant correlations between degrees of small-bowel mucosal morphologic damage in CD. Patients with IgA-tTG levels>160U/mL virtually always have CD, whereas the disease can be histologically absent in a significant number of patients with low serum tTG level. In our study, strongly positive antibody levels (IgA-tTG>160 units) were highly specific (>97%) for Marsh 3c lesions. We also noted that GI symptoms were more common in patients with lower IgA-tTG compared to patients with elevated levels. Alterations of laboratory parameters were particularly evident for the parameters expressing intestinal malabsorption, reasonably reflecting a more severe impairment of intestinal absorptive function in patients with villous atrophy.

The relationship between specific antibody level, degree of mucosal damage and clinical presentation in CD remains controversial. In the article by Taavela *et al*, the ratio of small-bowel villous height to crypt depth and results from serology tests correlate with the reported symptoms and quality of life of patients with CD. Patient-reported outcomes are therefore of value, in addition to histology findings, in assessing patients with CD (22). Mubarak *et al*. aimed to investigate whether CD patients with tTG levels ≥100 U/mL are different from patients with lower tTG levels. Patients with high tTG levels had lower average body weight-for-height standard deviation scores than did patients with lower tTG levels. In the low tTG group, GI symptoms were more common; specifically, abdominal pain and nausea were more frequent among patients with low tTG. In contrast, patients with solely extra intestinal manifestations were only present in the high tTG group (23). Dahlbom *et al*. demonstrated that high levels of IgA-tTG antibodies were associated with the grade of mucosal villous atrophy and a more severe clinical presentation. The combined measurement of IgA-tTG enables a noninvasive prediction of small intestinal villous atrophy with high accuracy, and may reduce the need for biopsy in patients with suspected CD (24).

Our study has some limitations. Our investigation is uncontrolled and retrospective but reflects current clinical routine practice. The inclusion of all adult CD patients over a 5 year- study period, with the availability of a small number of cases forms nonetheless the basis for future prospective studies to create a national CD patient database to access reliable information responding to the specific needs of the Romanian society and provide knowledge and even prevention tools (25).

CONCLUSIONS

Our study confirms the chameleonic na-

ture of CD. Adult Celiac disease is currently much more common than previously estimated and there is a need for well-designed epidemiological studies to increase detection rate. Celiac disease is confirmed to be more prevalent in female than in male patients (F:M = 3:1). IgA tTG levels correlate with duodenal villous atrophy in adult CD patients. An IgA-tGA level >160 was nearly always associated with CD histopathology. GI and non-GI symptoms are not reliable predictors of CD. No single clinical feature on its own is a reliable predictor or risk stratifier for CD.

GIANT CELL MYOCARDITIS: A BRIEF REVIEW

Giant cell myocarditis (GCM) was first described in 1905 and is characterized by a mixed myocardial infiltrate with multinucleated giant cells and cardiomyocyte necrosis. In larger autopsy series, the incidence of GCM has been reported to range from 0.007% to 0.051%. Given that autopsies are not routinely performed on an unselected population, and patients dying of GCM may not undergo autopsy, it is likely these figures underestimate the true incidence. In the United States in the 1990s, a group of major heart failure referral centers reportedly diagnosed GCM (via autopsy, endomyocardial biopsy, apical wedge resection, or cardiac explantation) an average of once every 21 months. Giant cell myocarditis is a rare, progressive inflammatory myocardial disease with high mortality, affecting a relatively young population. Although much progress has been made during the past decades in understanding the pathophysiology, there are still many deficiencies in our knowledge. Rapid diagnosis is critical, as the management differs from that of other myocardial processes containing giant cells, and early institution of combined cyclosporine-based immunosuppression can dramatically impact the disease course. Promising future directions include the development of serum biomarkers and utilization of gene expression profiling to potentially more rapidly diagnose and monitor GCM progress (Xu J and Brooks EG. Giant Cell Myocarditis: A Brief Review. Archives of Pathology & Laboratory Medicine 2016, 140 (12): 1429-1434).

CLINICAL SIGNIFICANCE OF VARIABILITY OF ATHEROGENIC INDEX OF PLASMA IN PATIENTS WITH lower limb peripheral arterial disease ON lipid-lowering therapy (abstract): Atherosclerosis, as the pathophysiological substrate of lower limb peripheral arterial disease (LLPAD), is a major health problem given the multitude of associated diseases and its severe course. Atherogenic index of plasma (AIP), defined as the logarithmically transformed ratio of concentrations of triglycerides (TG) to HDL-cholesterol is one of the main evaluation parameters of the atherosclerotic process, its variability being an important predictive factor of treatment response. **Aim**: The evaluation of clinical significance of AIP in patients with LLPAD on lipid-lowering therapy with statins and fibrate association. **Material and methods**: Retrospective study of a group of 160 patients aged 40 to 89 years diagnosed with LLPAD and on lipid-lowering treatment with statins and fibrate, hospitalized at the Cardiovascular Rehabilitation Clinic of the Iaşi Rehabilitation Hospital. During the 2 study years (January 1st, 2012-December 31st, 2013), the subjects received daily a constant maximum therapeutic dose of statin and fibrate. Demographic and anthropometric variables were considered and serological parameters were evaluated (total cholesterol-TC, TG, HDL-cholesterol, LDL-cholesterol and AIP) both before and after starting the treatment. In addition, the following symptoms were evaluated on a scale of 0 to 10 at the beginning and at the end of the study: intermittent claudication, feeling of cold feet, paresthesia. **Results and discussion**: There were significant reductions in TC, TG and implicitly in AIP levels. Analysis of clinical response showed that patients who achieved an AIP under 5 (117 cases-73%) experienced a significant reduction of symptoms, associated with a change in disease staging classification; in patients with an AIP over 5 (43 cases-27%) no variations of symptoms were recorded, the previous staging classification remaining unchanged. **Conclusions**: A 2-year constant dose of statin and fibrate combination in patients with LLPAD is associated with a decrease in AIP levels and correlates with symptoms reduction and improvement in the disease staging classification. Thus, an adequate control of lipid profile has beneficial effects on the clinical manifestations of LLPAD. **Keywords**: ATHEROGENIC INDEX OF PLASMA, LIPID-LOWERING THERAPY, LOWER LIMB PERIPHERAL ARTERIAL DISEASE, ATHEROSCLEROSIS.

Peripheral artery disease (PAD) comprises a multitude of different diseases in terms of etiology and pathogenesis that have in common damage to lower and up-

per extremity arteries (1). This group of diseases includes the chronic peripheral artery disease of lower limbs and its acute form (acute peripheral arterial occlusion), thromboangiitis obliterans (Buerger's disease) and the functional vascular disorders: Raynaud's disease, acrocyanosis, livedo reticularis. *Lower Limb Peripheral Arterial Disease* (LLPAD) is an obstructive disease that causes progressive narrowing of the lumen and decreased blood flow to the limbs, atherosclerosis being the most common cause (2). The prevalence of arterial occlusive diseases is dependent on age and sex, men over 70 years with multiple cardiovascular risk factors being most commonly affected. The prevalence of PAD in Romania varies directly with age, from 2.5% in the population aged 40-59 years to 18.8% in the population aged 70-79 years (2, 3).

The clinical picture of LLPAD includes a multitude of symptoms, the most important being intermittent claudication, paresthesia and cold feet. Of these, intermittent claudication is the key element in Leriche-Fontaine classification, as follows: stage I-asymptomatic; stage IIA -intermittent claudication after more than 200 meters of walking; stage IIB-intermittent claudication after less than 200 meters of walking; stage III-rest pain; stage IV-ischemic lesions: ulcers, gangrene, necrosis (4, 5, 6).

Atherogenic index of plasma, defined as the logarithm of the ratio between the concentration of triglycerides (TG) and HDL-cholesterol is one of the main benchmarks of the atherosclerotic process and hence of LLPAD, the variability of which is an important factor of predictability of treatment response (7, 8).

MATERIAL AND METHODS

A single-center, observational, descriptive and retrospective study was conducted on a sample of 160 subjects aged 40 to 89 years, hospitalized at the Cardiovascular Rehabilitation Clinic of Iasi Rehabilitation Hospital between January 1st, 2012 and December 31st, 2013. Inclusion criteria for the study were: LLPAD stage II (A or B) or III, a baseline TG level of more than 150 mg/dL, TC level over 220 mg/dL and HDL cholesterol under 35 mg/dL, absence of lipid-lowering therapy at study initiation. Exclusion criteria were: LLPAD stage I or IV, normal TG level, HDL-cholesterol level over 35 mg/dL and TC under 220 mg/dL, lipid-lowering medication. During the 2 years of study, the subjects received constant daily maximum therapeutic dose of statin and fibrate. Demographic variables, anthropometric and serological parameters (TC, TG, HDL-cholesterol, LDL-cholesterol, AIP) were assessed both before and after starting treatment. The following symptoms have also been evaluated on a scale of 0 to 10: intermittent claudication, cold feet, paresthesia, both at the beginning and end of the study.

The obtained data have been processed using *SPSS 21.0* (SPSS, Inc., Chicago, IL, USA).

RESULTS

After clinical examination, the patients included in the study were stratified according to Leriche-Fontaine classification as follows: stage IIA-20 (12.5%) patients, stage IIB-67 (60.6%) patients, stage III-73 (26.8%) patients (fig. 1).

At the end of the two years of study, after a constant daily maximum dose of statin and fibrate, the distribution of patients according to disease stage was: stage IIA-107 (66.8%) patients, stage IIB-40 (25 %) patients, and stage III-13 (21.6%) patients (fig. 2).

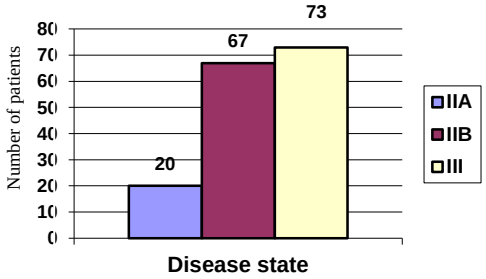

Fig. 1. Distribution of patients according to disease stage at baseline

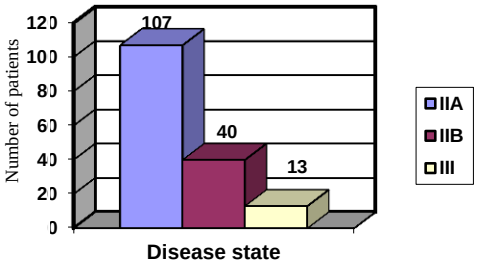

Fig. 2. Distribution of patients according to disease stage at study endpoint

The data obtained and illustrated in the above figures show that, as a result of the treatment administered during the two-year study, 30 patients (18.7%), previously staged as stage III, were reassigned as stage II, while 87 patients (54.3%), previously staged as stage IIB, were reassigned as stage IIA.

As mentioned above, every symptom present on admission (paresthesia, intermittent claudication and cold feet) were evaluated on a scale of 0 to 10, with 0 meaning the absence of symptom and 10 the highest intensity. During the study, revaluations were performed every 6 months, significant improvements in the grades of the patient being recorded (fig. 3).

Thus, a total of 110 patients (68.7%) showed an improvement by least two points on the pain scale (fig. 4).

Regarding AIP, at the end of the two-year study a significant number of patients (117/73%) had a decrease in value below 5, while in a smaller percentage (43/27%) the value remained above 5 (fig. 5).

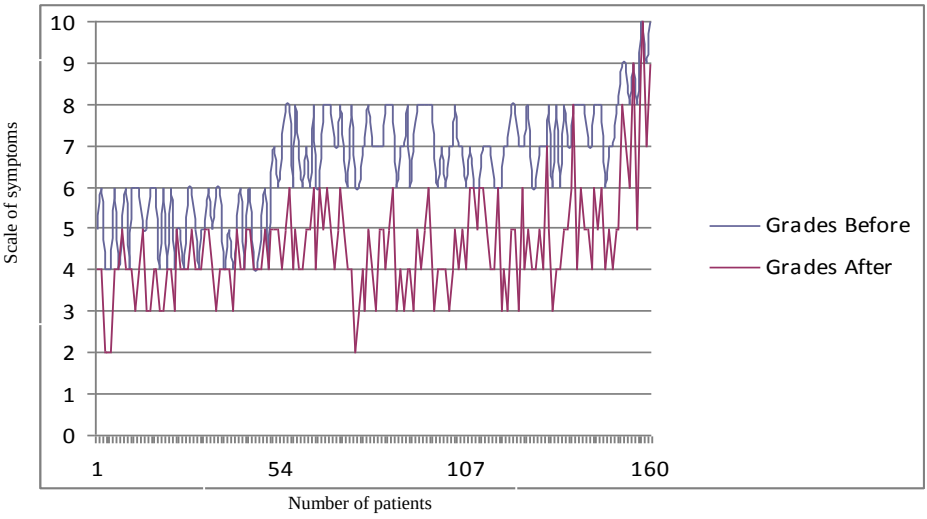

Fig. 3. Change in disease staging

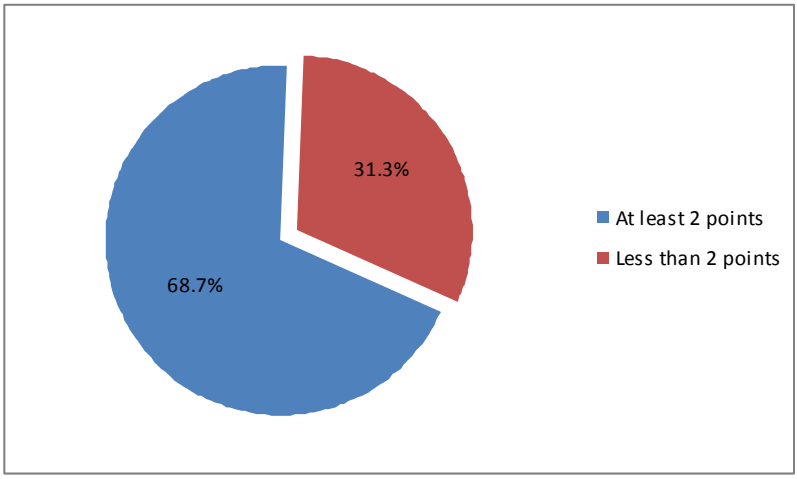

Fig. 4. Improvement on the pain scale

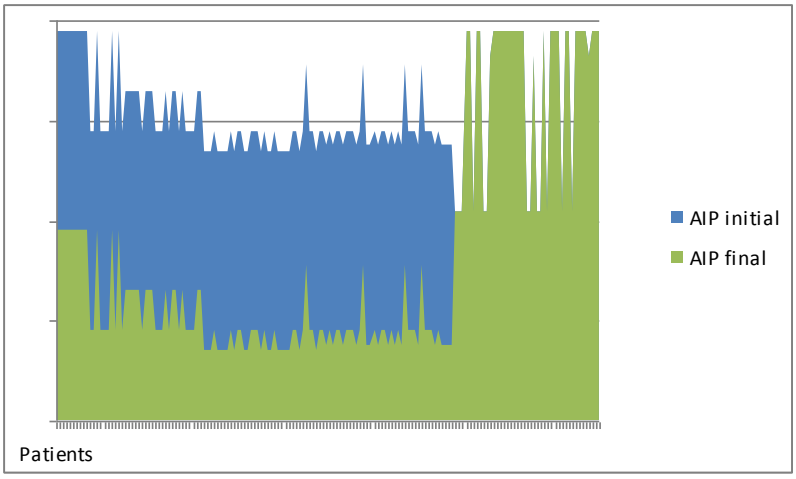

Fig. 5. AIP variability during the study

DISCUSSION

The process of atherosclerotic lesion formation is slow and remains asymptomatic until lumen compromise or vascular occlusion (9, 10). The pathophysiological processes involved are enhanced as well by classical risk factors for developing PAD: cigarette smoking, hypertension, diabetes and hyperlipidemia (11). Lipid abnormalities are known to have a critical role in the development of atherosclerosis, so that the administration of lipid-lowering medication has beneficial role both in preventing the occurrence of atherosclerotic lesions and in slowing the pathophysiological processes, with default improving of symptoms (12, 13).

Although the main goal of lipid-lowering therapy is to reduce the LDL-cholesterol levels, it is well known that high levels of TG and TG-rich lipoproteins (TRLs) are a cardiovascular risk factor

(14). On the other hand, hypertriglyceridemia is associated with low HDL-cholesterol levels; thus, although the lipid-lowering therapy is not targeted at correcting the HDL level, it is used to reduce hypertriglyceridemia (15). In the literature, there are case reports of patients with normal TG levels associated with low HDL-cholesterol (16, 17, 18). Due to the fact that HDL-cholesterol level is a marker of cardiovascular risk, uncorrelated with the atherogenic process, its isolated correction is not associated with a decreased risk (19). Recent studies have shown that aggressive treatment with lipid-lowering agents (maximum therapeutic dose) is associated with better prevention of cardiovascular events (20).

CONCLUSIONS

The present study demonstrates the efficacy of lipid-lowering therapy with statin and fibrate in constant maximum therapeutic doses administered for 2 years in patients with stage II and III LLPAD. Thus, there was a significant reduction of symptoms associated with improvement in disease staging, through the improvement of the lipid profile and therefore a decrease in AIP.

NEW PROTECTIVE ROLE OF IL-22 IN *MYCOBACTERIUM TUBERCULOSIS* INFECTIONS

In a study by Treerat *et al*., the functional role of IL-22 pathway in immunity against *Mycobacterium tuberculosis* strains was assessed. A member of the IL-10 cytokine family, IL-22 has both protective and pathological functions on mucosal surfaces. The study used as a prototype *M. tuberculosis* HN878, a member of the W-Beijing lineage and showed that the microorganism stimulates IL-22 production, using a TLR2 dependent mechanism. The study showed that IL-22 mediates protective immunity in chronic stages of infection in mice and that IL-22-dependent pathway in macrophages and epithelial cells mediate protective mechanisms for infection control (Treerat P, Prince O, Cruz-Lagunas A, Muñoz-Torrico M, Salazar-Lezama MA, Selman M, *et al.* Novel role for IL-22 in protection during chronic *Mycobacterium tuberculosis* HN878 infection. Mucosal Immunol. 2017 Mar 1. doi: 10.1038/mi.2017.15.).

POLYCYSTIC OVARY SYNDROME, A COMPLEX ENTITY INVOLVING REPRODUCTIVE AND METABOLIC IMPAIRMENTS (Abstract): A SYSTEMATIC REVIEW (Abstract): We attempt to synthesize main data in what concerns pathogenesis, signs and symptoms, diagnosis and management of polycystic ovary syndrome PCOS. The issue was the systematization of main data regarding different features of PCOS and stressing its peculiar association with characteristics of metabolic syndrome, main diagnostic criteria and most important therapeutic options, finally contouring an updated general picture of PCOS. We pointed also on associated morbidities, such as endometrial cancer, insulin resistance and need for individualized therapy, including changing in lifestyle, especially weight loss.
Keywords: POLYCYSTIC OVARY SYNDROME (PCOS), INSULIN RESISTANCE, ANOVULATION, HYPERANDROGENEMIA, GLUCOSE TOLERANCE TEST (GTT).

Polycystic ovary syndrome (PCOS), also known as Stein-Leventhal syndrome or hyperandrogenic anovulation is characterized by irregular menstrual periods or amenorrhea, hirsutism, acne, infertility and *acanthosis nigricans* (1).

The syndrome was first described in 1935 by American gynecologists Irving F. Stein and Michael L. Leventhal, giving the initial name of Stein-Leventhal syndrome. The earliest description of the disease dates back from 1721 in Italy (2).

In 2010, World Health Organization has estimated the syndrome being present in 116 million women all over the world, 3.4 % of the female population.

Ultrasonography has found polycystic ovaries in 8-25 % of normal women (3, 4).

ETIOLOGY AND PATHOGENESIS

Genetic factors are strongly involved in the genesis of the disease. Evidences include: hereditary features of PCOS, familial clustering and greater concordance in monozygotic than in dizygotic twins (5).

The disease is transmitted on an autosomal dominant way; in women with the allele, the phenotype is revealed by high androgen levels originating in the techa cells of the ovarian follicles. The precise affected genes have not yet been identified, but accumulated data suggest that the syndrome is a complex multigenic disorder (6).

The severity of the PCOS symptoms seems to be related to obesity and features of metabolic syndrome, since symptoms of PCOS are partially reversible, thus supporting the overlapping with main traits of metabolic syndrome (3).

The cysts in the ovaries are a symptom of the disease and not its primary cause; recent data is featuring the syndrome as a multisystem disorder with primary hypothalamic hormonal dysregulation. The term of disease is used to describe the situation in which ovarian cysts are evident in ultrasonography, while the term of syndrome is rather describing a complex condition with a wide spectrum of symptoms and presenting ovarian cysts in only 15 % of the cases (7).

Main pathogenic issue is represented by the overproduction of androgens, especially testosterone generated by the high levels of luteinizing hormone (LH) and hyperinsulinemia, in women whose ovaries are peculiarly sensitive to insulin (6, 8).

The increase of hypothalamic GnRH pulses results in an elevated LH/FSH ratio. Most PCOS cases show insulin resistance and/or obesity. Elevated insulin levels are triggering features of PCOS since are increasing the frequency of GnRH pulses. Increased LH/FSH ratio is inducing ovarian androgen overproduction, decreased follicular maturation and low SHBG binding, leading to the development of PCOS. Aromatase present in the adipose tissue is converting androstenedione into estrone and testosterone into estradiol; obesity is responsible for both overproduction of androgens (causing hirsutism and virilization) and estrogens (inhibiting FSH secretion) (9).

Chronic inflammatory mediators are believed to be involved in the development of different symptoms of PCOS, such as anovulation (10).

DIAGNOSIS

Diagnosis of polycystic ovary syndrome is based on two of the three criteria: anovulation, high androgen levels and ovarian cysts in ultrasound examination (Rotterdam criteria established in 2003).

Common signs and symptoms of PCOS are represented by: menstrual disorders, more often oligomenorrhea or amenorrhea, but other menstrual disorder may also be present; infertility caused by chronic anovulation; high levels of androgens resulting in acne and hirsutism, sometimes determining hypermenorrhea, alopecia or other symptoms; metabolic syndrome with central obesity and signs of insulin resistance (3, 11).

Diagnosis may be established exclusively on clinical signs, such as the history of menstrual pattern, obesity, hirsutism and acne (12).

Ultrasonography should demonstrate presence of small ovarian cysts resulted from the so called follicular arrest, in which several follicles reach a size of 5-7 mm, but they do not develop furthermore. No follicle reaches the pre-ovulatory size of at least 16 mm.

Recent studies support the opinion that at least 25 such follicles should be present in an ovary, in women aged 18-35 years, to confirm the ovarian morphology of PCOS. The cysts must appear in periphery of the ovary, showing the aspect of a string of pearls (13).

An ovarian volume of at least 10 ml is also considered a criterion for the PCOS morphology, besides the presence of cysts. Laparoscopy may put in evidence a thickened, pearl-white surface of the ovary.

Plasma elevated androgen levels (androstenedione and testosterone) is also a common finding in the polycystic ovary

syndrome. 60% of PCOS patients show high free testosterone levels.

Free androgen index: ratio of testosterone to sex hormone-binding globulin (SHBG) is correlating to the degree of obesity. Among obese PCOS cases, low levels of SHBG are common. Anti-Müllerian hormone shows high levels in PCOS; this may become a diagnostic criterion (14).

Insulin resistance demonstrated by abnormal two-Hour oral glucose tolerance test (GTT) is present in 15-33 % of women with PCOS; insulin resistance is appearing in overweight, as well as in normal weight subjects. Diabetes is associated in approximately 65% of women with the disease.

Elevated insulin levels are a common finding; insulin resistance in such cases is revealed at GTT (GTT insulin levels) by higher insulin levels and lower blood glucose, than in fasting condition.

Glucose tolerance test is a better diagnostic tool than fasting glucose in PCOS, since while fasting glucose may be normal, oral glucose tolerance is impaired in 38 % of the asymptomatic cases (15).

Differential diagnosis should consider different other causes of amenorrhea and virilization: hypothyroidism, congenital adrenal hyperplasia (21-hydroxylase deficiency), Cushing's syndrome, androgen secreting tumors or hyperprolactinemia.

MANAGEMENT AND PROGNOSIS

Therapy includes changing in lifestyle, medications and surgery.

Main aims of the therapy are consisting in reducing insulin resistance, recovery of fertility, therapy of hirsutism and acne; obtaining regular menstruation and prevention of endometrial hyperplasia and endometrial cancer.

Significant controversies are ruled out in what concerns optimal therapy, especially because of the lack of therapies comparing large-scale clinical trials. Weight loss is the most effective method in restoring normal ovarian function (ovulation, menstruation). Unfortunately, many women found it difficult to achieve. There are studies which are pointing on low glucids diets, which are bringing greater benefit in what concerns regular menstruation (16).

Medications used in the treatment of PCOS are especially oral contraceptives and metformin (oral hypoglycemiants).

Oral contraceptives are increasing SHBG levels and thus the binding of free testosterone. In this way are improved symptoms of hirsutism and normal menstruations are appearing. In many cases besides treating insulin resistance, metformin is effective in restoring ovarian function and normal ovulation. Spironolactone is also used for its antiandrogenic effects (17).

For anovulation (cause of infertility in PCOS) besides recommended weight loss, ovulation inducting medications are used: clomiphene-citrate and FSH (19). Metformin was also used in the treatment of anovulation but was found to be less effective than clomiphene; an important aspect in what concerns the use of metformin is that is not increasing the risk of birth defects (18).

In vitro fertilization may be used in case of non-responsiveness to clomiphene therapy.

Laparoscopic procedure consisting in puncturing 4-10 small cysts using electrocautery or laser, known as ovarian drilling is used for its result in restoring normal ovulation, yet there are controversies in what concerns the long-term effect of this

surgical procedure (19).

Anti-androgen drugs, such as flutamide and spironolactone are used to treat hirsutism. At the same time, metformin may reduce hirsutism possibly by diminishing insulin resistance, for this being used in the treatment of associated conditions such as diabetes and obesity (17).

The risk of endometrial hyperplasia and endometrial cancer through hyper stimulation of the uterine lining by estrogens, might be induced also by associated conditions such as obesity, hyperandrogenemia (20).

Insulin resistance and type II diabetes are commonly associated with PCOS, even in the cases with normal body mass index (7, 21).

Other associated conditions in PCOS are including: dyslipidemia non-related to insulin resistance; depression and anxiety; cardiovascular disease; hepatic steatosis; *acanthosis nigricans* and autoimmune thyroiditis (22, 23).

CONCLUSIONS

In our evaluation, besides its direct related pathology, PCOS is drastically affecting life quality; the need for changes in lifestyle (diet, physical exercise) does not need any more to be stressed; however, the difficulty in adopting different living habits makes from PCOS a subject of continuous challenge for patients, as well as for physicians.

NEW DEVELOPMENTS IN THE APPROACH AND DIAGNOSIS OF SARCOPENIA (Abstract): Sarcopenia, the key point of frailty syndrome, leads to decreased physical activity, with important consequences upon the quality of life in elderly. The prevalence of sarcopenia is still uncertain because of the lack of homogeneity of the studied populations, and also because of the variety of techniques. The development of biological markers that can be used in a cost effective manner to guide diagnosis and facilitate monitoring patients with sarcopenia, would mark an important step in managing the care of geriatric patients. Nutrition combined with physical activity is the key component of the management of sarcopenia, with a synergistic effect that helps combat malnutrition and improve the quality of life. **Keywords**: SARCOPENIA, BIOMARKER, NUTRITION, VITAMIN D.

Sarcopenia is defined as the loss in muscle mass and strength that occurs with age, generating a decrease in physical activity. It causes a progressive decrease in muscle mass of about 8% per decade by age 40-70 years, and of 15% after the age of 80. This condition affects 30% of patients over 60 years of age and about 50% of those over 80 years old (1).

The factors that contribute to the development of sarcopenia are multiple: physical inactivity, vitamin D deficiency, chronic inflammatory status, hormonal changes (low testosterone levels) and neuromuscular changes (decrease in the number of muscle fibres and motor neurons). The consequences will be severe, as the decreased muscle mass and strength will lead to a decline in physical activity, increased body instability and risk for falls and ultimately depression, poor quality of life and disability.

The decline in physical activity due to sarcopenia leads to a decrease in physical strength and force and will eventually lead to sedentary life and dependency with direct implications on quality of life and an increased risk of disability (2).

Sarcopenia decisively influences the risk of falls and fractures in older people: nearly half of accidental deaths in people over 65 are related to falls and their consequences (prolonged immobilization, respiratory tract infection) (3).

Unlike cachexia, that occurs secondary to a chronic disease, usually neoplasia,

sarcopenia refers to a decrease in muscle mass, not necessarily associated with weight loss (4). Thus, the concept "sarcopenic obesity" was introduced, where muscle tissue is infiltrated by fat tissue, in addition to excess subcutaneous fat, which translates to lower quality muscle fibre and muscle strength. Sarcopenia is a reliable marker of global presence of fragility syndrome (5). However, sarcopenia can lead to frailty, but not all sarcopenic patients are frail.

DIAGNOSIS

Decreased muscle mass makes the diagnosis of sarcopenia. The discrepancy between muscle mass and strength makes the assessment of muscle mass alone insufficient (6). Longitudinal studies have shown that the decline in muscle strength far exceeds changes in muscle mass, particularly in patients with constant body weight. In addition, preservation of muscle mass does not prevent the sensation of muscle weakness in the elderly (7).

The prevalence of sarcopenia is still uncertain because of the lack of homogeneity of the studied populations, but also because of the variety of techniques used to assess muscle mass. Full body scan by Dual X-Ray Absorptiometry (DXA) is currently considered the golden standard for assessing muscle mass (8). Other methods are bioelectrical impedance analysis, computed tomography (CT), magnetic resonance imaging (MRI), each of them providing objective and reliable information on muscle mass and fat (9). Unfortunately, such imaging equipment is not always available. In addition, MRI and CT examinations are quite expensive. Also, each of these techniques provides different estimates of body composition profile in terms of anatomical regions, making it difficult to compare the results (10). These and other drawbacks limit their use in routine practice. Muscle mass is only one dimension of sarcopenia. The functional decline arising from muscle coordination and balance disorders are clear signs of aging, which significantly affect the quality of life (11).

Muscle strength can be easily measured through performance tests: Short Physical Performance Battery (SPPB), 4-meter walk test, handgrip strength test. These tests can be significantly influenced by comorbidities that are often present in older people, mainly through inflammatory or degenerative osteoarticular diseases (12). While assessing the combined muscle mass and strength is a prerequisite for identifying sarcopenia, one of the biggest current problems is to define thresholds to differentiate between "physiological" and "pathological" aging (13). This limits the applicability of imaging tests and biomarkers in clinical practice and research.

The development of biological markers that can be measured in body fluids, used in a cost effective manner to guide diagnosis and facilitate monitoring patients with sarcopenia, would mark an important step in managing the care of geriatric patients.

Recent studies show that the combination of biochemical assays with imaging methods increase the accuracy of sarcopenia detection (12). However, the list of biomarkers proposed is very long and includes markers of inflammation (CRP, IL-6 and tumor necrosis factor TNF-alpha), urinary creatinine, hormone levels (testosterone, insulin-like growth factor 1, vitamin D), markers of oxidative stress. It was recently proposed a new set of serum markers directly associated with changes in skeletal muscle mass and function.

N-terminal peptide of type III procollagen (P3NP) (10) seems to be correlated with muscle remodeling after lifestyle change, exercise done consistently (14) or after hormone therapy with testosterone or growth factor (15). Framingham Offspring study conducted on 687 people showed that P3NP levels were related to total muscle mass in postmenopausal women but not in elderly men, therefore this biomarker is highlighted as a gender restrictive one (16).

C-terminal Agrin Fragment (CAF) (17) seems to be a reliable marker in skeletal muscle mass assessment. Excessive cleavage of the native motor neuron-derived agrin by neurotrypsin into a C-terminal Agrin Fragment (CAF) leads to functional disintegration at the neuromuscular junction and may consecutively cause sarcopenia. Elevated plasma levels of CAF were correlated with impaired neuromuscular junction, which in turn is involved in fiber denervation, muscle atrophy and dysfunction (18).

Similar to CAF, plasma concentrations of extracellular heat shock protein 72 (eHsp72) were inversely related to muscle mass and function (19). Production of eHsp72 has been correlated with inflammation (20) and the phenomenon of apoptosis. However, its implication in the development of sarcopenia is currently unclear.

Listed parameters and their partial association with pathophysiological processes involved in the development of sarcopenia underline the idea that we cannot consider the existence of a single biomarker. Comorbidities (cardiovascular disease, chronic renal disease, diabetes, lung disease, cancers) can also influence the biomarkers.

In conclusion, a complex approach can provide useful information about the pathophysiological mechanisms that lead to frailty and sarcopenia, with further implications in prevention or therapeutic strategies.

PREVENTION AND TREATMENT OF SARCOPENIA

Screening elderly people in order to detect those at risk of malnutrition is the key point and involving geriatricians, nutritionists and physiotherapists is essential.

In 2008 the Society for Sarcopenia, Cachexia and Wasting convened an expert panel to develop a guide of nutritional recommendations for prevention and management of sarcopenia. It concluded that protein and calorie intake is key measures associated with appropriate resistance training and aerobic exercises. However, nutritional management for sarcopenia remains unknown, recommendation ranging from one study to another.

1. PROTEIN INTAKE

In 2015, Rizzoli reported their recommendations for optimal protein intake from 1.0 to 1.2 g / kg, with an equal distribution for each meal (21).

Paddon-Jones et al. have proposed a diet plan that includes 25 to 30 grams of high quality protein per meal. In addition, adding to the diet 15-20 grams of whey proteins has increased the effects of exercise on muscle (22).

The intake of proteins and amino acids remains the most important anabolic stimulus of lean muscle tissue. Previous studies demonstrated anabolic effect of essential amino acids, particularly the branched chain (leucine). The β-Hydroxy β-Methylbutyrate (HMB), is a metabolite of the amino acid Leucine that, along with KIC (α keto-isocaproate) and isovaleryl-CoA, mediate the effects of leucine. Approximately 5% of dietary leucine is oxi-

dized into HMB, and HMB appears to be the main metabolite of leucine that more effectively prevents the breakdown of muscle protein. HMB is proposed as a potential food supplement for patients confined to bed for a long period of time (23), but further studies are needed.

In addition, diets supplemented with amino acids and carbohydrates consumed one hour after physical exercise increase muscle protein synthesis.

2. PHYSICAL ACTIVITY

Exercise is another important aspect in the prevention and management of sarcopenia. There are four types of recommended exercise, depending on the particularities of each elderly. Endurance exercises have a positive effect on the cardiovascular system. Strength training increases muscle mass and combined with nutritional supplements, improve muscle strength. Complex or simple balance exercises standing on one leg with eyes closed and hand support may decrease the risk of falls. Flexibility exercises, such as yoga or stretching can help prevent or recover from falls (24). Regardless of the type of exercise, it is recommended practicing them at least three times a week.

Nutritional intake combined with exercise has a synergistic effect that helps combat malnutrition and improves the quality of life. Physical activity should be recommended but in different intensity and complexity depending on age and possibilities of travel. Patients should be evaluated by a physiotherapist in order to assess range of motion, strength and endurance and to determine the need of using assistive devices such as canes, grab bars, shower seats.

3. VITAMIN D

Vitamin D deficiency is also frequent in older people, regardless of race or ethnicity. The level of 25-hydroxy vitamin D (25) (OH) decreases with age and is associated with muscle weakness. Dosing of vitamin D should be made to all person with sarcopenia, followed by adequate treatment (doses sufficient to increase the level of over 100 nmol/L) (25). The effects were observed in postmenopausal women. Doses up to 50,000 IU of vitamin D2 or D3 per week are allowed. But recent studies show that increased doses do not provide additional benefits compared to usual doses (26).

CONCLUSIONS

The analysis of recent literature makes us conclude that sarcopenia is a fundamental element in the diagnosis of frailty syndrome. According to our results, the geriatric evaluation must include the evaluation of sarcopenia, in order to assess the response to treatment and the evolution of frailty. From our experience several nutritional supplements, such as whey protein, amino acids (leucine, glutamine), vitamin D appear to be beneficial in promoting healthy muscle mass.

NEWS

ORGANOPHOSPHATE PESTICIDES DURING PREGNANCY AND NEUROLOGICAL DEVELOPMENT DURING EARLY CHILDHOOD

The authors studied prenatal exposure to organophosphate pesticides, which are ubiquitous in the environment, and child's neurological development. The study was conducted between 2003-2006 on a sample of 327 pairs mother / infant in Cincinnati, Ohio, to determine if there are associations between prenatal exposure to organophosphate pesticides and neurodevelopment in children. In pregnant women, urinary concentrations of metabolites of organophosphate pesticides and non-specific concentrations diethylphosphates, dimethylphosphates and dialkylphosphate were measured twice. In children, Bayley Scales of Infant Development, Second Edition-Mental and Psychomotor Developmental indices at the age of 1, 2, 3 years, the Clinical Evaluation of Language Fundamentals-Preschool, Second Edition, at age 4, and the Wechsler Preschool and Primary Scale of Intelligence, Third Edition, at age 5. Mothers with higher urinary total dialkylphosphate concentrations reported higher levels of socioeconomic status and an increased fresh fruit and vegetable intake. The authors found no association between prenatal exposure to organophosphate pesticides and cognition in children aged 1-5 years. It is possible that higher socioeconomic status and a healthy diet protect the fetus from potential side effects of exposure of pregnant women to organophosphate pesticides or that dietary exposure to metabolites is harmless or not an ideal measure of exposure to the parent compound. (Donauer S, Altaye M, Xu Y, Sucharew H, Succop P, Calafat AM, Lanphear B, Yolton K. An observational study to evaluate associations between low-level gestational exposure to organophosphate pesticides and cognition during early childhood. *Amer J Epidemiol* 2016; 184, 5, 410-418)

NEW CLASS OF DRUGS: THERAPEUTIC RNAi INHIBITION OF PCSK9 AS A SPECIFIC LDL LOWERING THERAPY (Abstract): Hyperlipidemia is a well-known risk factor for coronary heart disease, the leading cause of death for both men and women. Current lipid-lowering treatment is not always efficient, therefore new pharmacological interventions that reduce LDL cholesterol (LDL-C) have been developed. This paper presents new class of specific LDL lipid-lowering drugs under investigation in phase II or III clinical trials. The inhibition of proprotein convertase subtilisin/kexin type 9 (PCSK9), a key enzyme in cholesterol homeostasis, improve the liver's ability to clear LDL from the plasma, reducing LDL-C levels. Currently, three monoclonal antibodies PCSK9 inhibitors (alirocumab, evolocumab and bococizumab) are evaluated in clinical outcome trials. ALN-PCSsc, the new first-in-class therapeutic RNA interference (RNAi) inhibitor of proprotein convertase subtilisin/kexin type 9 (PCSK9) is also the first-in-class investigational medicine that acts by turning off PCSK9 synthesis in the liver. The development leadership of ALN-PCSsc has now transferred from Alnylam Pharmaceuticals® to The Medicines Company, who has initiated the ORION-1 Phase II study at the beginning of 2016. ALN-PCSsc has significant potential given its highly competitive profile as compared with monoclonal antibodies anti-PCSK9 MAbs, a recently approved class of LDL-C lowering drugs. **Keywords**: RNA INTERFERENCE (RNAi), PCSK9 PROTEIN, ALN-PCSsc.

Hyperlipidemia is a well-known risk factor for coronary heart disease, the leading cause of death for both men and women. Current lipid-lowering treatment is not always efficient, therefore new pharmacological interventions that reduce LDL-C have been developed.

The inhibition of proprotein convertase subtilisin/kexin type 9 (PCSK9), an enzyme discovered almost a decade ago (1) as a key player in cholesterol homeostasis (2,3,4), is now considered an exciting approach (5,6,7) in the reduction of the incidence of cardiovascular events (8,9,10). The PCSK9 protein is a plasma protein synthesized by several organs in the body (liver, intestine, etc.) and it can bind to LDL receptors. This binding prevents the LDL receptors from continuously clearing LDL from the plasma, resulting in elevated LDL-C levels. The new class of drugs, PCSK9 inhibitor drugs, serves to improve the liver's ability to clear LDL from the plasma, reducing LDL-C levels and reducing the risk of cardiovascular diseases.

When added to a maximized statin regimen, PCSK9 inhibitors work synergistically with statins to provide additional LDL-lowering via a different mechanism of action (11). The progress from PCSK9 discovery to the development of targeted treatment (12, 13) has been unprecedented in terms of scale and speed. The first suggestion of a link between PCSK9 and hypercholesterolemia was published in 2003 (14); a decade later, two meta-analyses of clinical trials comparing anti-PCSK9 treatment to placebo or ezetimibe, including >10,000 hypercholesterolemic individuals, were published (15). This paper presents new groups of lipid-lowering drugs under investigation in phase II or III clinical trials.

PCSK9 INHIBITION WITH MONOCLONAL ANTIBODIES

Currently, three PCSK9 inhibitors (all anti-PCSK9 MAbs: alirocumab, evolocumab and bococizumab) are being evaluated in clinical outcome trials and the results will determine the future of these lipid-lowering therapies by establishing their clinical efficacy in terms of cardiovascular event reduction, safety, and the consequences of prolonged exposure to very low levels of LDL-cholesterol. Irrespective of their outcomes, the exceptionally rapid development of these drugs exemplifies how novel technologies, genetic validation, and rapid clinical progression provide the tools to expedite the development of new drugs.

Hypercholesterolemia is a condition characterized by very high levels of cholesterol in the blood which is known to increase the risk of coronary artery disease, the leading cause of death in the world. However, a large proportion of patients with hypercholesterolemia are not achieving adequate LDL-C levels with currently available therapies such as statins, including genetic familial hypercholesterolemia patients, acute coronary syndrome patients, high-risk patient populations (e.g., patients with coronary artery disease, diabetes, symptomatic carotid artery disease, etc.) and other patients that are statin intolerant. There is a significant need for novel therapeutics to treat patients with hypercholesterolemia whose disease is inadequately managed by existing therapies. One potential drawback of monoclonal antibodies and other PCSK9 inhibitors in development is the need for repeated injections of the drugs.

PCSK9 INHIBITION WITH RNA INTERFERENCE (RNAi) INHIBITORS

In efforts to reduce the number of injections required for effective treatment, Alnylam Pharmaceuticals® and The Medicines Company recently reported positive results from their phase I clinical trial with ALN-PCSsc, an investigational RNAi therapeutic targeting PCSK9 which would likely be dosed quarterly. RNAi (RNA interference) is a revolution in biology, representing a breakthrough in understanding how genes are turned on and off in cells, and a completely new approach to drug discovery and development. Its discovery has been heralded as "a major scientific breakthrough that happens once every decade or so," and represents one of the most promising and rapidly advancing frontiers in biology and drug discovery today which was awarded the 2006 Nobel Prize for Physiology or Medicine. RNAi is a natural process of gene silencing that occurs in organisms ranging from plants to mammals. By harnessing the natural biological process of RNAi occurring in our cells, the creation of a major new class of medicines, known as RNAi therapeutics, is on the horizon (16).

Small interfering RNA (siRNA), known as short interfering RNA or silencing RNA, the molecules that mediate RNAi and comprise Alnylam's RNAi therapeutic platform, target the cause of diseases by potently silencing specific mRNAs, thereby preventing disease-causing proteins from being made (fig.1). RNAi therapeutics have the potential to treat disease and help patients in a fundamentally new way (17, 18, 19).

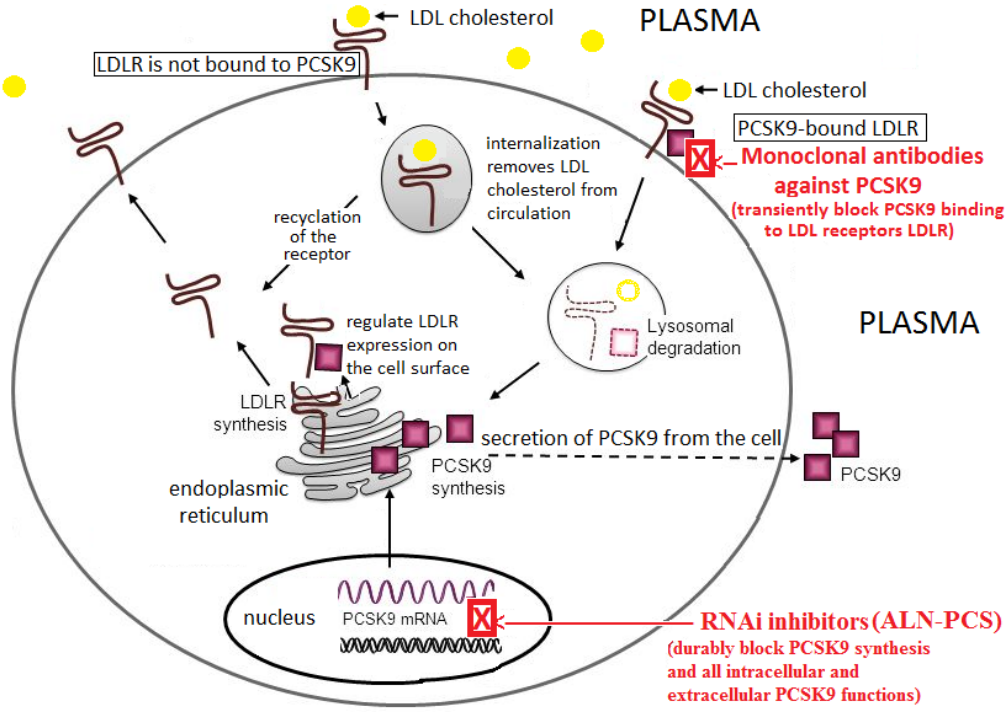

Fig. 1. PCSK9 Therapeutic Hypothesis [Adapted from (17)]

New delivery platforms were introduced for ALN-PCSsc. GalNAc-siRNA conjugates are a proprietary Alnylam delivery platform and are designed to achieve targeted delivery of RNAi therapeutics to hepatocytes through uptake by the asialoglycoprotein receptor. Alnylam's Enhanced Stabilization Chemistry (ESC)-GalNAc-conjugate technology enables subcutaneous dosing with increased potency and durability, and a wide therapeutic index. This ESC-GalNAc-conjugate delivery platform is being employed in nearly all of Alnylam's pipeline programs, including ALN-PCSsc and several other programs in clinical development (20).

PHARMACOLOGYCAL EFFECTS

The effects of ALN-PCSsc were found to be highly durable, with clinically significant and clamped reductions in LDL-C, supportive of a potential bi-annual subcutaneous dose regimen. Specifically, an up to 53 percent maximal and 47 percent least squares mean reduction in LDL-C was achieved at day 180 after just a single, low volume injection (tab I). In addition, ALN-PCSsc was shown to reduce a number of

atherogenic lipids, including lipoprotein (a) - or "Lp(a)" - and total cholesterol, which are associated with increased risk of cardiovascular disease. ALN-PCSsc was generally well tolerated with no clinically significant drug-related adverse events, but it is not known the long-term clinical benefit (21).

TABLE I
Comparative efficacy of MAbs and RNAi inhibitors of PCSK9

Study name	PCSK9 inhibitor	Dosing	LDL-C reduction vs. placebo
ODYSSEY (7)	Alirocumab	300 mg once-monthly	56%
RUTHERFORD (7)	Evolocumab	420 mg once-monthly	55%
Ballantyne et al.(7)	Bococizumab	300 mg once-monthly	27–53%
ORION-1 (18)	ALN-PCSsc	500 mg on days 0 and 90	59%

CONCLUSIONS

These anti-PCSK9 agents, now in phase II or III clinical trials, are still years away from approval. These new drugs appear to be promising in the reduction of the incidence of cardiovascular events because they reduce LDL-C, but there are basic facts not understood. Although the current recommendation for PCSK9 inhibitors is to be used in conjunction with statins and they have a steep price compared to statins, there are still not enough data about their long-term safety and efficacy and about the place of PCSK9s in the treatment of hypercholesterolemia.

ETHICAL AND GENETIC ASPECTS REGARDING PRESYMPTOMATIC TESTING FOR NEURODEGENERATIVE DISEASES (Abstract) Neurodegenerative diseases, such as Alzheimer's dementia, Huntington's chorea, Parkinson's disease or spinocerebellar ataxia, manifests into adulthood with an insidious onset, slowly of progressive symptoms. All of these diseases are characterized by presimptomatic stages that preceded with many years of clinical debut. In Parkinson's disease, more than half of the dopaminergic neurons of the black substance are lost before the advent of motor characteristic manifestations. In Huntington's chorea, the progressive neurodegenerative disease could be diagnose prenatal and presymptomatic by analyse of the number of CAG repeats in exon 1 of the huntingtin gene. A similar mechanism represented by expansion of trinucleotide repeats during hereditary transmission from parents to children was identified in fragile X syndrome, spinocerebellar ataxia, spinal muscular and bulbar atrophy, or myotonic dystrophy. Presymptomatic diagnosis in all these progressive diseases raise many ethical issues, due to the psychological impact that can cause the prediction of a disease for which there is currently no curative treatment. Therefore, a positive result can produce serious psychological trauma and major changes in the lifestyle of the individual, instead, a negative result can bring joy and tranquillity. But the problem arises if presymptomatic testing in these neurodegenerative diseases brings greater benefits compared to the possible psychological damage, which can add the risk of stigmatization or discrimination. **Keywords**: NEURODEGENERATION, DYNAMIC MUTATION, PRESYMPTOMATIC TESTING, ETHICS ASPECTS.

Neurodegenerative diseases (ND) are hereditary or sporadic conditions characterized by progressive nervous system dysfunction, often associated with atrophy of central or peripheral nervous system structures. They are a heterogeneous group of age-associated, chronic illnesses of varying aetiologies, the main challenges for healthcare systems, including informal care and long-term care facilities, in the coming decades (1).

ND had a bad prognosis, after a period of 7–12 years of progressive deterioration of multiple areas of brain, including memory, reasoning, communication and the skills needed to carry out daily activities (2).

The recent discoveries of disease-causing genes in neurodegenerative diseases have generated considerable interest and debate for both physicians and patients regarding routine genetic testing of some ND in the clinic. Molecular genetics provide a powerful tool in the diagnosis of many neurodegenerative diseases and can help better define and classify many of the heterogeneous inherited neurodegenerative disorders. Genetic testing could allow early confirmation of diagnosis and appropriate institution of genetic counselling, but also may provide a genotype-phenotype correlation, select specific patients for clinical drug trials, and offer a better understanding of pathogenesis of the disease (3). Pre-symptomatic testing is usually performed at risk-population and investigate a person with a clear-cut family history, who has no symptoms of ND at the time of testing (4) and looking for genetic mutations that have a high penetrance, such as homozygous or compound heterozygous mutations in recessively inherited genes (e.g. *PINK1* and *DJ1* genes, in Parkinson's disease) or dominantly inherited mutations *(*like *SNCA* or *LRRK2* genes, in Parkinson's disease*)* (5).

Various positions have been advanced regarding the issue of predictive genetic testing for unpreventable or untreatable adult-onset disorders (6). On the basis of a medical benefit argumentation, some have argued that the absence of measures to prevent the disease or its complications or to treat the disease is a reason not to perform this test (7). Although still acknowledging the importance of medical benefit as a justification for predictive genetic testing, it has been recognized that in exceptional circumstances to apply the predictive test could be better than wait that child will arrive in adulthood (8).

Often, the communication of genetic information is a difficult issue and may have a powerful psychosocial impact on the child and its parents. Thus, in the case of a positive test, children could present anxiety or depression, and the parents could present a feeling of guilty. This process could be complicated by several factors. Usually, genetic testing is made only one time during the life and could have important consequences. Thus, the individual needs to think very carefully before deciding to take such a test. In majority of diseases is still not an ideal biomarker able to improve differential diagnosis, track disease progression and measure treatment efficacy and the method could have not conclusive results or be genetically uninformative (7, 8).

However, the feasibility of routine genetic testing of ND in the clinic is still fraught with many unanswered questions. “Which gene must be analysed in a particular case?” “Which clinical features are more adequate to select patients for genetic testing?” “Is the sensitivity and specificity of the genetic test high enough?” “Which are the consequences of a positive or ambiguous result?” “Which will be the patient's and physician's attitudes in case we will discover a genetic abnormality?” (6).

Genetics of neurodegenerative diseases

Alzheimer's disease

Alzheimer's disease (AD) is the most prevalent ND, accounting 50-70 % of all dementias. In a report of Commission of the European Communities, from 2009 is estimated that 7,300,000 peoples from Europe present AD and probably in 2020 the number will be double (9). The pathogenic mechanisms imply structural and chemical changes in the brain, leading to the death of neurones. For late-onset AD

cases the mechanism implies interaction of multiple genetic and environmental factors. Early-onset (before age 65) AD tends to cluster within families, but represents only 10% of AD (10). Among these, one half is caused by a heritable mutation in gene encoding one of 3 proteins: presenilin-1 (PS1), presenilin -2 (PS2), or amyloid precursor protein (APP). All these mutations are dominant, and the carriers develop AD in nearly 100% of cases. For multifactorial forms the most important gene seems to be the gene of apolipoprotein E (APOE). The gene is located on chromosome 19 and presents three variants: APOE ε2, APOE ε3 and APOE ε4. Only APOE ε4 has been validated, by genetic linkages, as an AD risk factor. The heterozygous for APOE ε4 have a 3-5 time higher risk, while homozygous for APOE ε4 have a 8-18 time higher risk for late-onset AD. However, a genetic test for APOE ε4 has little predictive value (11, 12).

Other genes which are linked to increased risk of AD are *CLU, PICALM, CR1, BIN1, ABCA7, MS4A, CD33, EPHA1* and *CD2AP*. Variants of these genes are linked to significant differences in risk of Alzheimer's, but their effects are much smaller than for APOE (10-13).

Despite the progresses concerning genetic, behavioural, cardiovascular, and nutritional risk factors, long-term prevention studies have yet to be conducted to see if the incidence of AD can be reduced.

Parkinson disease

Parkinson disease (PD) is characterized by a loss of dopaminergic cells in the *substantia nigra pars compacta* and the presence of Lewy bodies (14). The recent new discoveries of a number of disease-causing genes (such as α-synuclein, parkin, *UCHL1, PINK1, DJ-1, LRRK2*) in PD have generated considerable interest for presymptomatic genetic testing of PD in the clinic. Early-onset autosomal-recessive PD forms were associated with mutation in *PINK1* and *DJ-1 (PARK7)* genes (15, 16). *LRRK2 (PARK8)* gene is implied in autosomal-dominant PD with similar phenotype to sporadic PD, but the brain changes generated by LRRK2 mutations are extremely variable. The most common mutation of *LRRK2* gene is G2019S substitution present in different populations worldwide. Other possible target genes are *PRSS25, UCHL1*, synphilin and *NURR1* (17). However, the promises and limitations of genetic testing in PD must be confirmed by detailed scientific studies, which will allow also guidelines and recommendations for such genetic testing.

Huntington disease

Huntington disease (HD) is a neurodegenerative, autosomal dominant disorder with late-onset, caused by the expansion of a CAG repeat in the first exon of the HD gene, located on chromosome 4p16.3. Usually symptoms begin in 30s or 40s decades by involuntary choreic movements, loss of voluntary control of movement, followed by cognitive impairment and personality disorder tending to depression, anger and temper outbursts (18).

The number of CAG repeats is correlated with clinic manifestation of the disease. Normal individuals have 6 – 26 CAGs (class 1) and the allele is stable. In the presence of 27–35 CAGs (class 2) phenotype is normal, but the allele is expandable during spermatogenesis. The individuals with 36–39 CAGs (class 3) have a phenotype with reduced penetrance. The presence of more than 40 CAGs (class 4) is associated with fully penetrated forms (19, 20).

The test for the HD gene is fast, rela-

tively inexpensive, and highly sensitive, with positive and negative predictive values approaching 99 percent. Genetic testing can be performed at any stage of development, even before the onset of symptoms. Many ethical aspects could be identified in the predictive testing of HD, like autonomy, beneficence, non-maleficence, inequality, paternalism or even medical errors. An example of ethical issue could be the case of monozygotic twins, when one brother would to apply the predictive test and other brother do not accept this. In this case is an ethical conflict between autonomy and coercion, but also is necessary to quantify which action is more beneficial: to know if mutation is present or to not know is the mutation is present (21).

Spinocerebellar ataxia diseases

Spinocerebellar ataxias (SCAs) constitute a large group of heterogeneous disorders characterized by a degeneration of the spinal cord and the cerebellum, that cause imbalance, poor coordination, and speech difficulties. Some types of ataxia are inherited, including dominantly inherited diseases and about 30 different gene mutations have been found. Among the more common inherited ataxias are *Friedreich's ataxia* and *Machado-Joseph disease.* Ataxia can also be acquired after stroke, multiple sclerosis, tumours, alcoholism, peripheral neuropathy, metabolic disorders, and vitamin deficiencies. One of the common genetic defects is an expansion of a CAG triplet repeat in genes that regulate the production of different proteins, but the number of CAG repeats varies among the different types of SCAs. Normal individuals with premutation have an increased risk of developing symptoms late in life and also to have abnormal children (22, 23). The correlation between the mutations and the disorders remains unclear, but one explanation may be that the encoded abnormal protein has a toxic effect on neurones, which are successively destroyed. Molecular genetic testing for CAG repeat length is a highly specific and sensitive diagnostic test (24). If the mutation is known in the family, prenatal diagnosis and pre-implantation diagnosis (PGD) are possible. Genetic testing is available for spinocerebellar ataxia types 1, 2, 3, 5, 6, 7, 8, 10, 12, 13, 14, 17, 28; dentate-rubro-pallidoluysian atrophy (DRPLA); ataxia-telangiectasia (A-T); Friedreich's ataxia (FRDA); Ataxia with oculomotor apraxia types 1 and 2; Marinesco-Sjogren Syndrome; Ataxia with Vitamin E deficiency; Fragile X associated tremor/ataxia syndrome (FXTAS); mitochondrial recessive ataxia syndrome (MIRAS); autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS); and Episodic ataxia types 1 and 2 (20, 22-26).

Particularities of genetic testing for a neurodegenerative disease?

In hereditary forms of ND genetic testing can be applied before or after the setup of symptoms. However, the test does not predict the age of setup and the evolution of disease. The major reason for undergoing testing is to find out for the sake of one´s children, or for family planning. However, the use of this test for the minor persons is denied, and the only exception is the presence of symptoms before the age of 18 (27).

Most clinical genetic units follow recommended guidelines or programmes, as the waiting process and dealing with the result are very stressful situations, both for the person tested and for the family. The guidelines indicate the need of several meetings with a multidisciplinary team

(that include a geneticist, a neurologist, a psychiatrist, an ethical counsellor) started by a preliminary meeting when the data from familial history is stored. After this meeting, follow a pretesting meeting (when are discussed the beneficial and the disadvantages of testing) and finally a meeting when are presented the results and are discussed the consequences (positive or negative) of genetic analyse. In the present, the diagnoses of ND are frequently made on clinical grounds, sometimes supported by radiological methods. The application of genetic testing for ND should be reserved to patients who have a family history of ND or those with very young age at onset (28-30).

Ethical aspects of genetic testing for adult-onset disorders and ethical aspects

Testing of young people for adult-onset disorders by presymptomatic and predictive genetic testing is the most controversial predictive testing because we have not any treatment that could prevent the onset and progression of the disease (30).

A big problem concerning presymptomatic genetic testing in high risk individuals for ND is related to answer to question - *Do people really want to know the truth?*. Other difficulties are related to collect DNA samples from relatives, who need neurological examination and genetic counselling, problems that rais complex psychological, ethical, legal and moral conundrums (31).

Presymptomatic genetic testing for neurodegenerative diseases generates some ethical conflicts. The authors identified four types of issues. First, in some ND exists juvenile form (for example HD) and this could complicate the decision to make or not the test. Second: in some diseases the preventive measures or the therapies are uncertain. Third: the best interest is interpretable; in some situation the best interest for child is not identical with best interest for family and in these situations the physicians must protect the rights of child in relation with family. And finally, the guidelines must be concordant with local legal or cultural context (32).

Most people have these tests in hopes of negative results, but inevitably, such hopes are often dashed by tests that come up positive. Many other subjects (in particular, those in families with a history of disease) choose to be tested so that, in the event of a positive test, they can make lifestyle changes or pursue clinical interventions that may alter the course of the disease to which they are predisposed. Unfortunately, a positive genetic testing for ND do not allow a preventive or curative treatment like in other diseases (i.e. breast cancer, colorectal cancer) and this could generate psychological trauma. Thus, a positive DNA test for HD or (early-onset) AD means that, if the person lives to middle or late middle age, the disease *will* manifest, and will be unstoppable once it does. This explains why in generally only about 15-25 percent of people at risk get tested (33).

For some ND, the pathogenic mechanism is linked to a variable amplification of DNA repeats sequences during vertical transmission and generates the phenomenon of anticipation. Also, the severity of the symptoms is correlated with the size of the amplification, but it is difficult to predict severity in a future generation based on mutation size in a parent (34).

Other problem that complicates the genetic testing in ND is the varied penetrance. For example, the penetrance of G2019S mutation associated with Parkin-

son's disease is highly age dependent, increasing from 17% at age 50 years to 85% at age 70 years (35).

So, in the absence of a possible clinical response, a test confirming or even suggesting future development of a fatal neurodegenerative condition can have a devastating psychological impact on the patient. These risks may include changes in the individual's perception of self, stresses in relationships with friends or family, discrimination in the workplace or community, difficulties obtaining or keeping insurance, unfavourable adjustment of disability benefits, and other concerns related to privacy and confidentiality. A positive result could be beneficial, because sometime is preferable to known that you have a certain type of mutation in opposition with the anxiety generated by the absence of a clear answer. Also, the result of genetic testing could profoundly influence patient decision making with respect to finances (i.e., providing for inevitable hospice care), family planning (i.e., marriage or reproduction), and fostering personal relationships. Finally, the weighing of risks and benefits of genetic tests is a decidedly personal endeavour (36).

Although, the guidelines for presymptomatic genetic testing in ND vary among countries, some key elements include the following steps: neurologic neuropsychologic and psychiatric evaluation, genetic counselling, sign informed consent document, psychological assessment, review of the potential impact of the test, disclosure of results in person and arrange post-result follow-up. For the testing will exclude patients with significant psychiatric disorders or those undergoing stressful life circumstances causing emotional upheaval. During the pre-test counselling should be provided the explanations concerning implications of positive and negative results. All DNA determinations must be carried out independently at least twice and the results will be analysed after a genetic linkage computer analysis of haplotypes (the data from relatives must be analyzed anonymously to prevent the transmission of inappropriate information). Usually, the process is long and need many counselling sessions as the patient needs a psychological support. If the patient agrees the idea to inform other members of family about its genetic status, the patient could be accompanied by a relative during a minimum one session and also for the disclosure session when the results will be communicated. The diagnostic information must be given in a face- to-face session, because patient needs to discuss what this information may mean, even if the outcome is genetically uninformative. Long-term follow-up is essential, particularly for those who test positive for the gene. The testing are applied only to persons aged 18 years or older, must be totally voluntary and the results remain totally confidential (9,30-36).

Conclusions

The neurodegenerative diseases represent a group of diseases with late onset, invariable evolution to neurological and cognitive degradation, have not yet any pathogenic therapy and have a genetic component more or less important. In some such conditions the predictive genetic testing before onset of symptoms is possible, but is not available for general population. Such testing may be useful where a family member has already been diagnosed to carry a known mutation.

The genetic testing must be preceded by a genetic counselling respectful of the reli-

gious and cultural perspectives and traditions of individuals. Genetic counselling is complicated by a multitude of aspects, such as the apparition of a de novo mutation in a negative history family or familial factors, such early parental deaths, adoption, and illegitimacy.

Although the medical advances will be inherent and hopefully beneficial to the persons suffering from ND, the psychological and social support by sensitive, timely, and accurate counselling will remain an essential aspect in presymptomatic genetic testing.

THE NEED FOR HBV GENOTYPING: A COST-EFFICIENT APPROACH (Abstract): The outcome of chronic HBV infection is variable; approximately one half of individuals transition to an inactive carrier state, 30% progress to cirrhosis, and the remainder to chronic hepatitis. Ten different HBV genotypes and many subtypes have been identified with distinct geographical distributions. Over the years, a lot of studies presented the efficiency of different genotyping methods; for this reason we aimed to present a cost efficient genotyping diagnosis algorithm of CHB infected patients, especially useful to identify those at risk of disease progression and determine optimal anti-viral therapy as useful instrument for physicians. **Keyword**s: HBV, CHRONIC HEPATITIS, GENOTYPE, ANTIVIRAL THERAPY.

More than one third of the world's population has been exposed to HBV, and approximately 350 million persons are chronically infected (1). Persons with chronic infection are at risk for the development of complications such as cirrhosis, hepatic failure, and hepatocellular carcinoma. In the US, 3050 cases of acute HBV infection were reported in 2013 (2); in the same year, 19 930 cases of HBV infection were reported in 28 EU/EEA Member State. 13 644 (68.5%) of these reported cases were chronic (ECDC); the true figure is estimated to be considerably higher (3).

Since 1984, universal newborn immunization and mass population screening and immunization programs have reduced the rate of chronic HBV infection and liver cancer in endemic regions (1). Persons at high risk of HBV infection should be tested for HBV (Management Guidelines) (4). Screening and diagnosis involve serology assays (detection of HBsAg and Anti-HBs, Anti-HBc (total antibodies and IgM type), HBeAg and Anti-HBe) and HBV DNA assays. These methods, together with the liver histology are used to establish the most suitable diagnostic algorithm.

In clinical practice, HBV DNA measurement is used to assess the state of HBV infection, stratify risk of disease progression to cirrhosis and hepatocellular carcinoma, aid in the decision to begin therapy, and monitor treatment efficacy and failure.

A serum HBV DNA level > 2000 IU/mL has been proposed as a cutoff level to differentiate patients with HBeAg-negative chronic hepatitis from those in an inactive carrier state (ie, hepatitis B e antigen – HBe Ag - negative, persistently normal alanine aminotransferase) (5).

10 different genotypes (and many subtypes) of HBV have been recognized and are designated by letters A-J HBV genotypes. These genotypes are recognized having different geographic distribution and they influences natural history, clinical outcomes, and response to therapy (6).

METHODOLOGY

This review has two objectives: 1. to present comparatively the HBV genotyping techniques in order to indicate the most sensitive and specific method and 2. to assess the clinical utility of HBV genotyping assays. We have searched the PubMed library using next key words: *hepatitis B virus, genotype, genotyping methods, antiviral therapy, chronic B hepatitis* and we have found 668 articles, from which 112 clinical trials. Our clinical question included several components: the Population, Intervention, Comparison, Outcome and Method (PICOM). The components of the clinical questions were: **P**atients – individual with chronic HBV hepatitis; **I**ntervention or exposure – HBV genotyping; **C**omparison – antiviral therapy efficiency according with the HBV genotype; **O**utcomes – decrease HBV DNA level, absence of HBsAg; **M**ethod of study design for this narrative review – controlled trials.

1. The HBV genotyping methods

The search of Pub Med data base using the key words *hepatitis B virus*, and *genotyping methods* revealed 301 articles, from which we selected 2 for analysing, the most representative of them (7, 8). The most common assays used for HBV genotyping were: Genomic sequencing and filogenetic analysis, INNO-LiPA, RFLP (*Restriction fragment length polymorphism*), Multiplex PCR (reacții PCR multiple), Serologic subtyping, *Oligonucleotide Microarray chips*, FT-RDB (*Flow-through reverse dot blot*), RFMP (*Restriction fragment mass polymorphism*), PCR *invader assay*, Real Time-PCR (table I). In terms of identifying mixed genotypes of the same sample, INNO-LiPA achieve excellent results (100%) in each study, contrast with genomic sequencing that can not detected the co-infection. However, this latter technique the "gold standard", is characterized by the ability of detection of mutations in the viral genome (100% results), for which INNO-LiPA results were obtained for 93.75% (6). Finally, the best consistent results (99.56%) was also obtained by these two techniques, INNO-LiPA and sequencing genome, which apparently are distinguished by their benefits and results. In terms of cost-benefit analysis, technique INNO-LiPA seems to be the most advantageous, this standing out for the price of low cost, high sensitivity, specificity 100%, use easy method, but the most important feature recommending this technique is the detection capability of mixed genotypes. The disadvantages of the technique can be translated as: cost price higher than PCR-based methods; low sensitivity to the presence of mutations in the sequences to be analyzed; it can reduce the effectiveness of the exogenous DNA contamination; inability to detect in a single reaction both the genotype and characteristic mutation, thus the time to result being increased two-times (7, 8).

Regarding subtypes of HBV genotypes, sequencing and phylogenetic analysis, proved their efficacy and accuracy, although sequencing not yet achieved the level of "gold standard" and from this point of view.

TABLE I

Comparison of HBV genotyping methods (7, 8)

Genotyping method	Se	Sp	Limit of detection	Advantage	Disadvantage
Genomic sequencing	100%	100%	4 x 10^2 UI/ml	Gold standard; detect the genotypes recombination	Expensive; can not be used at large scale
INNO-LiPA	100%	100%	1 x 10^3 UI/ml	Cheaper than sequencing; high specificity	Expensive in comparison with serological assays; time consuming
RFLP	87%	100%	2 x 10^3 UI/ml	Simple technique; cost efficient; can be used in large populational studies	The polimorfism of nucleotides for the prime affect sensitivity
Multiplex PCR	99%	100%	-	Simple technique, cost effcient; can be used in large populational studies	The polimorfism of nucleotides for the prime affect sensitivity
Serologic subtyping	-	-	1 x 10^2 UI/ml	No needed PCR, simple technique, cost efficient	The polimorfism of nucleotides for the prime affect sensitivity
Real Time-PCR	99%	100%	500 IU/ml	Low risk for contamination of samples; high sensitivity; can be analyzed a high number of samples.	Low capacity to distinguish between genotypes with closed temperatures of denaturation

*Se – sensibility, Sp - specificity

2. HBV genotype influence of viral therapy in CHB patients

Therapy for HBV infection currently includes interferon and nucleos(t)ide analogues (NA) that inhibit HBV polymerase. Five nucleoside / nucleotide analogues are currently approved for HBV treatment: lamivudine, telbivudine, adefovir, entecavir, and tenofovir. Targeting other steps in the viral life cycle (eg, encapsidation and viral entry), stimulating the innate immune response, and therapeutic vaccination, as well as RNA interference–based strategies are currently under investigation.

Numerous studies have reported differences in the natural history, clinical outcomes, and responses to therapy based on hepatitis B virus (HBV) genotype (9, 10). Data show that patients infected with genotype B achieve better clinical outcomes than patients infected with genotype C, including lower disease activity, a younger age at hepatitis B e antigen (HBeAg) seroconversion, a higher chance of sustained remission after HBeAg seroconversion, and a reduced risk of hepatocellular carcinoma (11). In addition, patients infected with HBV genotypes A and B have been shown

to have higher rates of HBeAg seroconversion when treated with peginterferon vs patients with HBV genotypes C and D (9). Genotype D has been correlated with the precore mutation leading to HBeAg-negative chronic hepatitis B (11).

TABLE II

The antiviral therapy in CHB patients according with HBV type (12 – 23)

Clinical trial author, year, no of cases	Given therapy	Genotype effect on antiviral therapy efficiency
Marcellin P, 2014, 266 CHB	tenofovir disoproxil fumarate (TDF)	The strongest independent predictors of HBsAg loss were Caucasian race with genotype A/D
Ito K, 2014, 212 CHB	nucleotide analogs (NAs)	The time to disappearance of HBsAg was significantly longer for genotype A patients than non-A genotypes
Sonneveld MJ, 2013, 803 CHB	peginterferon (PEG-IFN)	The response rates were low in patients with genotypes A or D and in comparison with genotypes B or C
Lampertico P, 2013, 128 CHB	peginterferon α-2a (PegIFN)	PegIFN treatment was well tolerated and the post-treatment virological response improved significantly (120 genotype D)
Sonneveld MJ, 2012, 221 CHB	PEG-IFN +/- lamivudine	On-treatment HBsAg decline significantly varied according to HBV genotype (A and B more than C and D).
Liaw YF, 2011, 544 CHB	peginterferon alfa-2a (PEG-IFNα-2a)	PEG-IFNα-2a treatment regimen was the most efficacious and beneficial for HBeAg-positive patients predominantly infected with hepatitis B virus genotypes B or C.
Gish RG, 2010, 354 CHB	entecavir or lamivudine	Caucasian patients, and those infected with HBV genotype A or D, were significantly more likely to lose HBsAg.
Lu HY, 2008, 71 CHB	lamivudine-IFN alpha-2b	HBV genotypes C and B had no obvious influence on intrahepatic HBV DNA load or cccDNA load.
Zou HB, 2007, 90 CHB	lamivudine and alpha-interferon	NO influence on the lamivudine treatment effects for the HBV genotype B and C CHB patients; alpha-interferon treatment for HBV genotype B CHB patients is more effective than that for the genotype C ones.
Lu HY, 2007, 71 CHB	lamivudine, IFN-alpha 2b	Intrahepatic HBV DNA level (before and after treatment) was not significantly affected by the patients' HBV genotype.
Luo K, 2007, 224 CHB	interferon-alpha (IFN-alpha)	NO significant differences in clinical characteristics and response to IFN-alpha between genotypes B and C were found
Yuen MF, 2006, 80 CHB	lamivudine	NO difference in treatment response between patients with genotype B and C.
Zhao H, 2007, 230 CHB	pegylated IFN-alpha -2b	HBV genotype B and patient age (< or =25 years) were 2 independent factors associated with sustained combined response.
Bonino F, 2007, 518 CHB	peginterferon alpha-2a +/-lamivudine / only lamivudine	In the peginterferon alpha-2a and lamivudine monotherapy arms, patients with genotypes B or C had a higher chance of response than genotype D infected patients, the latter responding better to the combination than to peginterferon alpha-2a monotherapy.
Flink HJ, 2006, 266 CHB	Peg-interferon alpha-2b.	Treatment with Peg-interferon alpha-2b is the best therapy to achieve HBsAg clearance in patients with genotype A.

From the 112 clinical trials only 15 full filed our search criteria. The given therapy (interferon / nucleotide analogues), the effect according with the HBV genotype can be observed in Table II. Although new therapies for hepatitis B introduced in the past 10 years have improved the efficacy of viral suppression and have lowered the risk of antiviral resistance, in certain patient populations, there remain complex issues surrounding hepatitis B prevention and treatment. For the second aim of this study we formulate the review question (PICOM) and we have included only clinical trials, like a proof of study quality. We need reviews in order to increase ***power*** to detect intervention effects, to prevent delay in the introduction of effective therapies, to better select and individualise therapy. The extracted data from these revealed that 5/15 clinical trials concluded that antiviral therapy efficiency was not influenced by the HBV genotype. The results of the remained 10 studies are not homogenous, but we still can appreciate that therapy with NA is more efficient for genotype A and D of HBV, and interferon therapy is having better outcome for B and C genotypes. Future studies will be necessary to support a final clear conclusion.

CONCLUSION

Although the WHO 2015 Report and US guidelines do not involve the HBV genotyping in evaluation of antiviral therapy of CBH patients (1, 24) we consider that according with consistent results of presented studies, the genotyping methods are useful in identify those patients at risk of disease progression and determine optimal anti-viral therapy, useful tool for practitioners. It is accepted that HBV genotype influences the prevalence of pre-core mutations, but the functional role of this mutation in liver disease is unclear. In the future, well designed studies will be necessary to evaluate the efficiency of interferon treatment *versus* NA therapy according with HBV genotype.

ARTERIAL HYPERTENSION IN THE ELDERLY – THE HEART OF THE MATTER (Abstract): Arterial hypertension is a public health issue that has not been completely solved from an epidemiological point of view in terms of its assessment and particular management. Poor data from trials allow only general recommendations limiting the decisions in clinical practice. Elderly hypertensives are a special group characterized by a particular blood pressure profile, most often an isolated systolic hypertension, and prone to orthostatic hypotension, pseudohypertension and blood pressure variability that impose strict rules and various methods of blood pressure measurement for making appropriate therapeutic decisions. The approach of the elderly hypertensive patient is also complex as it requires rigor and flexibility, well-balanced choice of therapy, careful, regular monitoring, polypharmacy avoidance, and a close relationship between the physician and the patient in order to increase compliance. **Keywords**: HYPERTENSION, ELDERLY, BLOOD PRESSURE MEASUREMENT, TARGET BLOOD PRESSURE.

Arterial hypertension (AH) in the elderly remains a topic of broad interest as disease prevalence is markedly increasing and it is the most important modifiable risk factor and predictor for cardiovascular morbidity and mortality. In this group of patients, AH management is closely related to the cardiovascular physiology and pathophysiology of aging. The most important issue is lack of objective data from trials. Frequently, age is an exclusion criterion and studies that include elderly have no specific results for this group. Clinical practice lacks a specific guideline and is currently based on recommendations from general guidelines for arterial hypertension. Actually, the only document addressing this problem is ACCF/AHA 2011 Expert Consensus Document on Hypertension in the Elderly (1).

ARTERIAL HYPERTENSION EPIDEMIOLOGY IN THE ELDERLY

AH prevalence has been increasing sharply in the elderly, a population that has undergone evident growth, especially in Europe and Japan. Data from a study that cumulates results from national registers of 6 European countries, US and Canada, shows that the AH prevalence in the elderly aged between 65-74 years, ranges between 53% for Canada and the US and 78% for Europe (2). SAGE study (Study on Global

Ageing and Adult Health) conducted by the WHO concludes the same trend in countries in Asia, Africa, South America and the Russian Federation (3). NHANES report indicates that rates of AH control in the elderly are low compared to the middle aged hypertensive adults, especially in patients older than 80 years (4). Framingham Heart Study data are consistent, as rates of controlled blood pressure (BP) are decreasing both in males and females with advancing age (38% for ages younger than 60 compared to 23 to 28% in patients aged over 80) (5). It seems that older women have a much higher prevalence of AH after 65 years, a situation worsened by poor rates of controlled blood pressure and unfavorable prognosis (6). Regarding the influence of race, NHANES data highlights the highest prevalence in black population compared with white population (40% versus 27%), highest stroke mortality, coronary artery disease and heart failure, as well as a lower rate of control (20.7% *vs.* 30%) (1). On the other hand, for the Asiatic elderly patients, it revealed a lower prevalence compared to the white race (16.1% *vs.* 28.5%), with a genetically influenced response to treatment among different subpopulations (1). Arterial hypertension epidemiology data in the elderly are non-homogeneous before and after 2000s due to disease definition. Changing the concept regarding the importance of systolic BP (SBP) for cardiovascular risk demonstrates the increase of isolated systolic hypertension (ISH) prevalence. BP behavior with age is not uniform as ISH appears as a separate clinic entity, but the BP profile can be also systolic-diastolic or isolated diastolic. Diastolic AH is a much more rare entity, occurring in less than 10% of hypertensives aged over 70 (1).

ARTERIAL HYPERTENSION AND CARDIOVASCULAR RISK

In the elderly, SBP irrespective of the increase in diastolic BP (DBP) maintains its role as a predictor of morbidity and mortality. Therefore, the risk of all-causes mortality increases by 1% for every 1 mmHg increase in BP (1). The risk is continuous for coronary heart disease, while SBP lowering doubles the absolute decrease in clinical events (7). The level of SBP is a better predictor of cardiovascular risk than DBP. For instance, MRFIF study shows that the incidence of cardiovascular events and mortality in grade 1 ISH is doubled compared to the optimal level of SBP (8), and the risk of stroke increases by 1.42 times in the Physician's Health Study trial. (9). Similarly, SBP Cardiovascular Health Study considers SBP as the best predictor of cardiovascular events and uncontrolled AH could explain 25% of coronary events (10). Cardiovascular risk in the elderly is influenced by almost constant association with other cardiovascular risk factors. Dyslipidemia is obviously more frequent and is a common therapeutic target with proven benefits, as ALLHAT-LLT trial demonstrates (1, 11). The prevalence of diabetes increases exponentially with age and remains an important predictor for progression of AH to heart failure at the age over 65 (12). Obesity and overweight increase the risk of AH especially in women (13), although the obesity paradox is discussed also in the elderly (INVEST study) (14). It discusses the role of hyperuricemia induced frequently by thiazide diuretics and complex causal relationship with osteoarticular diseases, accompanied by an excess of cardiovascular morbidity and mortality caused by AH (52% to 73%) (1).

PATHOPHYSIOLOGICAL FEATURES

In the elderly, the arterial system shows changes similar to the hemodynamic effect of AH at younger ages. In hypertensive patients, atherosclerosis being initially an adaptive process is accompanied by inflammation and endothelial dysfunction, the substrate of vulnerable plaques and acute atherothrombotic complications (15). Direct functional consequences are decreased flow-mediated vasodilation and baroreceptor sensitivity correlated to the level of SBP. The process of arteriosclerosis, age-specific and accelerated by AH, is responsible for arterial stiffness, characterized by thinning and fragmentation of elastin, collagen deposit growth, Ca^{2+} ions fixing (16). For small arteries, atherosclerosis is the consequence of vascular remodeling with increased pulse pressure and peripheral vascular resistance. Changes are especially evident in coronary arteries and blood vessels in the circle of Willis. Arterial stiffness is the tisular biomarker of early vascular aging syndrome (EVA) and reflects the influence of age-associated cardiovascular risk factors on the arterial wall (17).

Arterial stiffness is frequently measured by pulse wave velocity, with pathological values > 13 m/s in the elderly. Arterial stiffness causes the increase of central BP, changes of the cerebral and renal local hemodynamics, cardiac structural and functional impairment. Basically, there appears an early reflection of pulse wave from proto-diastole to tele-systole with aortic SBP amplification and direct effect on heart-vessel coupling (left ventricular hypertrophy - LVH). At the same time it causes a reduction of DBP, pulse pressure amplification, and therefore, damage of coronary and myocardial perfusion. In the kidney, decrease of distensibility of juxtaglomerular apparatus, reduction of the ability to produce renin at any level of Na^+ input, damage of the ATP-dependent Na^+-K^+ pump occur. Specific to the elderly is the inability of rapid Na^+ excretion after an increased intake, increased sensitivity to salt and growth of BP. Increased sensitivity to salt is caused by the generation of natriuretic substances, such as dopamine and prostaglandin E2, as well as insufficiency of an inhibitor of Na + pump called marinobufagenin (18,19). Alpha-ducin cytoskeletal protein modulates the sodium balance, the BP level, the elastic properties of the arteries, and explains the complicated evolution of hypertension by coronary heart disease or stroke (20). It has been shown that the diurnal variation in glomerular filtration is absent in the elderly, affecting the chrono-pharmacological profile of renal excreted drugs. The reduction of renal mass and a decrease in aldosterone production it is also associated with impaired potassium excretion (1, 21). Another feature in the elderly is the hyperactivity of catecholamines, reduced sensitivity of target-organs to noradrenaline, increased activity of alpha-receptors. It results in a poor vasodilation, to which also contributes low parasympathetic activity. These changes are less correlated with the BP per se, but rather with its variability. Overall, the elderly hypertensive patient has a particular hemodynamic profile, characterized by normal cardiac function at rest but with a tendency to decreased function during exercise, slight tendency towards bradycardia, predominant increase of SBP, hypervolemia and decreased activity of plasma rennin, accentuated variability of BP.

CLINICAL AND EVOLUTIVE FEATURES

Accurate office BP measurement is extremely important and is required by par-

ticular aspects as orthostatic hypotension (OH), pseudohypertension, BP variability (22, 23, 24). BP difference between arms is common (about 20% of cases) and SHEP study finds the increased frequency of OH (17.3% to 26%), having an impact on mortality, risk of stroke and dementia (25). Postprandial OH is another specific and frequent feature, caused by the inadequate response to vasodilator effect of gastrointestinal peptides and insulin, and reported in 70% of the elderly aged over 70 (26). Detection of pseudohypertension in the elderly with false resistant AH is also important. This phenomenon found in the elderly is defined as an artificial increase of BP due to stiffened arteries that cannot be adequately compressed during the cuff inflation. Electronic gauges or "finger" type devices are useful technical alternatives (Finapres) (1). AH and white coat-effect (15-25%), masked AH (21-45%), BP variability ("non-dipper" or "extreme-dipper" profiles) are also more frequent, and in this case ambulatory BP monitoring acquires a special importance (27). The prognostic value of the method is supported by multiple studies. Each increase by 10 mmHg of daytime and night-time SBP increases the risk of cardiovascular death by 10% and 18% respectively. Awakening and bed-time increase of SBP are related with long-term cardiovascular complications. A parameter with prognostic significance for mortality is also the ambulatory arterial stiffness index (28,29). Home BP measurement, although having a particular importance, cannot be used properly because of frequent physical and mental disabilities or associated arrhythmias, so measurement errors are common in the elderly (30). Overcoming these common problems in the elderly would be possible by using memory devices, telemonitoring or smart phone applications (1).

Recommendations for the diagnosis of secondary forms of AH are generally similar to other age groups, although the onset in the elderly is rare. The onset of disease in elderly patients, sudden worsening of previously well-controlled AH, resistant AH are the main clinical scenarios for a secondary form. Inadequate life style may increase SBP and induce pseudoresistance. Smoking has the most aggressive impact and frequent use of NSAIDs remains significant by determining 1.82-times higher risk of AH (1).

In terms of clinical evolution, geriatric AH often is characterized by unpredictable outcomes, 3 to 4 times higher frequency of myocardial infarction or ischemic stroke (1), simultaneous impairment of cognitive function up to vascular dementia (35% *vs.* 13% in non-dippers *vs.* dippers) (31). Meta-analysis of 31 randomized trials in adults and elderly does not show the superiority of one therapeutic class (32), but the early initiation of treatment clearly influences clinical outcomes (PROGRESS, SHEP, Syst-Eur cit. by 1). Heart failure is closely related to AH, LVH being a determinant mechanism. The studies reported up to 82% incidence in elderly over 65, with a high frequency of preserved systolic function form of heart failure (22.6%) mainly determined by myocardial ischemia and diabetes (Lakki E cit. by 1). The association of peripheral arterial disease accelerates the progression of the disease, so the attention should be focused on screening strategy (PREVALENT study) (33). SBP is an independent predictor for renal function decline in the elderly with ISH. In turn, renal dysfunction correlates independently with risk of heart failure and is more common in diabetic patients (1).

THERAPEUTIC APPROACH

The two recently published guidelines for the management of AH (23,24) provide the same recommendations on initiation of antihypertensive drug therapy in the elderly (tab. I).

TABLE I

Recommendations for initiating antihypertensive treatment in the elderly

(adapted after 23, 24)

2013 ESH/ESC Guidelines	2014 JNC8th
Initiation	***Initiation***
- BP ≥ 160 mmHg (I A) - BP 140-159 mmHg (< 80 years old) if therapy is well-tolerated (IIb C)	- SBP ≥ 150 mmHg or DBP ≥ 90 mmHg
BP target	***BP target***
- < 80 years old: SBP 140-150 mmHg (I A); SBP < 140 mmHg may be considered in some patients, but generally depending on individual tolerabiity (IIb C) - > 80 years old – SBP 140-150 mmHg (I B)	- < 150/90 mmHg (grade A) - if SBP < 140 mmHg is well-tolerated, the adjustment of therapy is not necessary (grade E – expert opinion)

Both guidelines underline lack of additional benefit of lowering SBP less than 140 mmHg for clinical outcomes, starting from the observation that in the trials this level of BP has not been reached (34). The same statement applies for "the very elderly" according to data of HYVET trial (35). Lacking the consistent data on the benefits/disadvantages of lowering SBP less than 140 mmHg, a prospective trial is currently ongoing. The estimated completion date is set for 2018, and the trial will enroll 10,000 patients aged over 55 followed-up 4 to 8 years. It aims to assess the impact on stroke, cardiac complications, progression of chronic kidney disease and age-related cognitive dysfunction. SPRINT Senior sub-study will enroll 1,750 participants over 75 years to assess whether benefits are similar (36).

In terms of clinical practice, it is important to lower BP slowly and gradually, with lower drug doses, carefully used to avoid tissue hypoperfusion, especially at the cerebral level. Intervention by non-pharmacological measures is mandatory as in any hypertensive patient. TONE trial offers reference information in this respect (37). It started in 1995 and it aims to assess the role of decreased sodium intake (daily less than 80 mEq), reduction of body weight (≥ 10 lb) or of both strategies in controlling BP level in treated hypertensive elderly patients (37). Weight loss of 3.5 kg in hypertensive patients aged 60-80 reduces BP on average by 4/1.1 mmHg. Salt restriction has an additive effect on lowering BP (average of 4.3/2 mmHg after 3 months) in combination with exercise and without medication. Two trials included in a large meta-analysis studying the role of potassium supplementation show that the BP reduction was consistent in the elderly (4.3 to 10 mmHg/1.7 to 6 mmHg) (1), although serum potassium levels should be closely monitored. The well-known DASH trial reveals the benefits of diet rich in fruits and vegetables, low in saturated fat at any age and presents the importance of sodium restriction. SBP decreased on average by 8.1 mmHg in hypertensive patients between 55-76 years compared with 4.3 mmHg in adults aged 23-41 (38).

General rules of pharmacotherapy in elderly patients are: start with small doses,

reduced by approximately 50% of the adult dose, with gradual and slow growth; doses are adjusted according to orthostatic BP, drugs that can cause OH are avoided as first-line choice (i.e. central sympatholytics); pseudoresistance should be considered but also the drugs that may enhance the antihypertensive effect (i.e. cimetidine, antifungals, grapefruit juice etc.); convenient therapeutic regimens are used, preferably with a single administration as to increase compliance, polypharmacy is avoided; attention is given to adverse effects as frequent comorbidities are associated. ESH/ESC guidelines states that all five classes of antihypertensive drugs may be recommended for initiation, but diuretics and calcium channel blockers (BC) remain the first option, while the JNC8th do not favor beta blockers. The initial selection of drugs in the elderly should especially take into account associated diseases (2/3 of hypertensive patients). An important aspect is the principle of combination therapy. In addition to the general benefits related to pharmacokinetics medication, the elderly is included by the cardiovascular risk scores systems into additional high and very high risk group. Therefore, the therapeutic scheme should include drugs with cardiovascular protective and antiatherosclerotic effects, such as ACE inhibitors and sartans drugs. There is no consistent data in new trials on the elderly patients. HYVET shows the favorable effect of the combination of ACE inhibitors-diuretics and ACCOMPLSH reports the superiority of the association of ACE inhibitors-BC (39). Fixed-dose combinations are a viable alternative both in uncomplicated and complicated AH for secondary prevention. A special mention should be made for octogenarians, in which effective treatment substantially reduces cardiovascular risk and mortality, similar to other age groups. In this case, it is preferred to start with one antihypertensive drug, and depending on response and individual tolerability, a second drug will be added. Low-dose thiazide diuretics may be used, BC and where appropriate, ACE inhibitors/sartans drugs are recommended with careful and regular monitoring. 2011 American Consensus recommended that SBP/DBPs levels are not lowered under 130/60 mmHg (1).

Compliance to treatment, a general problem in AH, becomes even more important in the elderly. Age is one of the major predictive factors of non-adherence, it is explainable because of an asymptomatic disease until cardiovascular complications appear, where polypharmacy, complicated therapeutic schemes, adverse effects, high-costs in socially disadvantaged patients with multiple comorbidities are common (40,41,42). A common reason of non-compliance is polypharmacy. Schall et al. show that the average number of drugs prescribed to American elderly patient is about 6, and antihypertensive drugs but also medication directly affecting BP is frequently included (40). A method of treatment improvement for clinicians has been the elaboration of an information system to correct prescriptions in the elderly (STOPP) and to develop individualized prescription (START) in order to fight polipharmacy (43). A second cause is deficiency in reaching blood pressure targets. Therefore, only 1 out of 3 patients continued treatment for hypertension after 1 year (44).

CONCLUSIONS

After consulting the dedicated literature, we can conclude that AH in the elderly is a complex issue for which evidence-based information is incomplete. We have at our disposal only recommendations provided by general guidelines for AH, based

primarily on observational data and the opinions of experts. AH prevention in the elderly is not standardized and optimal therapy remains a sensitive issue that requires clinical experience and individualization. In addition, the elderly should be correctly defined and consequently the therapy optimized.

NEW PERSPECTIVES IN THE DIAGNOSIS AND TREATMENT OF CHILDHOOD FEBRILE EXANTHEMAS (Abstract): A child with a febrile exanthema is a complex medical problem involving diagnostic challenges, epidemiological threats and a great concern for the parents and any physician, should be prepared to deal with it. Many of the classical ones (measles, rubella, chickenpox) have now a decreased incidence due to a high vaccine coverage, which makes even harder for the physician to establish an early diagnosis. To the untrained eye most of them are difficult to differentiate. Their prompt recognition is necessary in order to manage them adequately and to prevent spreading of the disease.
Keywords: RASH, BLISTERS, ANTIBODIES.

The majority of the febrile exanthemas of the childhood have viral origin and have autolimitant spontaneous evolution. Even that, through its frequency, epidemiological implications and potential viral, bacterial or immunologic complications, these represents an important and delicate medical and epidemiologic problem. Due to high vaccination coverage, some of them are now rarely seen.

MEASLES

Measles, also known as morbilli, is an infection of the respiratory system, immune system and skin caused by a virus, specifically a paramyxovirus of the genus *Morbillivirus*. Symptoms usually develop 7–14 days (average 10–12) after exposure to an infected person and the initial symptoms usually include a high fever (often > 40 °C), Koplik's spots (spots in the mouth, these usually appear 1–2 days prior to the rash and last 3–5 days), malaise, loss of appetite, hacking cough (although this may be the last symptom to appear), runny nose and red eyes (1). After this a spot-like rash comes, covering much of the body. The course of measles, provided there are no complications, such as bacterial infections, usually lasts about 7–10 days. Measles is an airborne disease that is spread through respiration (contact with fluids from an infected person's nose and mouth, either directly or through aerosol transmission via coughing or sneezing), and is highly contagious-90% of people without immunity

sharing living space with an infected person will catch it. An asymptomatic incubation period occurs nine to twelve days from initial exposure. The period of infectivity has not been definitively established, some saying it lasts from two to four days prior, until two to five days following the onset of the rash (i.e., four to nine days infectivity in total), and whereas others say it lasts from two to four days prior until the complete disappearance of the rash. The rash usually appears between two and three days after the onset of illness.

The classic signs and symptoms of measles include four-day fevers and the three Cs-cough, coryza (head cold), and conjunctivitis along with fever and rashes (2). The fever may reach up to 40 °C. Koplik's spots seen inside the mouth are pathognomonic for measles, but are not often seen, even in confirmed cases of measles, because they are transient and may disappear within a day of arising. Their recognition, before the affected person reaches maximum infectivity, can be used to reduce spread of epidemics.

The characteristic measles rash is classically, described as a generalized, maculopapular, erythematous rash that begins several days after the fever starts. It starts on the back of the ears and, after a few hours, spreads to the head and neck before spreading to cover most of the body, often causing itching. The measles rash appears two to four days after the initial symptoms and lasts for up to eight days. The rash is said to "stain", changing color from red to dark brown, before disappearing. Complications with measles are relatively common, ranging from mild and less serious complications such as diarrhea to more serious ones such as pneumonia (either direct viral pneumonia or secondary bacterial pneumonia), otitis media, acute encephalitis and corneal ulceration (leading to corneal scarring). Complications are usually more severe in adults who catch the virus. In underdeveloped nations with high rates of malnutrition and poor healthcare, fatality rates have been as high as 28%. In immuno compromised persons the fatality rate is approximately 30%. Clinical diagnosis of measles requires a history of fever of at least three days, with at least one of the three C's (cough, coryza, conjunctivitis). Observation of Koplik's spots is also diagnostic of measles. Alternatively, laboratory diagnosis of measles can be done with confirmation of positive measles Ig M antibodies or isolation of measles virus RNA from respiratory specimens. In patients where phlebotomy is not possible, saliva can be collected for salivary measles-specific Attesting Positive contact with other patients known to have measles adds strong epidemiological evidence to the diagnosis. The contact with any infected person in any way, including semen through sex, saliva, or mucus, can cause infection. There is no specific treatment for measles. Most patients with uncomplicated measles will recover with rest and supportive treatment. It is, however, important to seek medical advice if the patient becomes more unwell, as they may be developing complications. Some patients will develop pneumonia as a sequel to the measles. Other complications include ear infections, bronchitis (either viral bronchitis or secondary bacterial bronchitis), and encephalitis. Acute measles encephalitis has a mortality rate of 15%. While there is no specific treatment for measles encephalitis, antibiotics are required for bacterial pneumonia, sinusitis, and bronchitis that can follow measles.

RUBELLA

Rubella, also known as *German measles or three-day measles*, is a disease caused by the rubella virus. This disease is often mild and attacks often pass unnoticed. The disease can last one to three days. Children recover more quickly. Infection of the mother by rubella virus during pregnancy can be serious; if the mother is infected within the first 20 weeks of pregnancy, the child may be born with congenital rubella syndrome (CRS), which entails a range of serious incurable illnesses. Miscarriage occurs in up to 20% of cases (3). The disease is caused by Rubella virus, a togavirus that is enveloped and has a single-stranded RNA genome. The virus is transmitted by the respiratory route and replicates in the nasopharynx and lymph nodes. The virus is found in the blood 5 to 7 days after infection and spreads throughout the body (4).

Rubella is a common childhood infection that is seldom fatal usually with minimal systemic upset although transient arthropathy may occur in adults. Serious complications such as deterioration of the skin are very rare. Apart from the effects of transplacental infection on the developing fetus, rubella is a relatively trivial infection. Rubella has symptoms that are similar to those of flu. However, the primary symptom of rubella virus infection is the appearance of a rash on the face which spreads to the trunk and limbs and usually fades after three days. The facial rash usually clears as it spreads to other parts of the body. Other symptoms include low grade fever, swollen glands (sub occipital and posterior cervical lymphadenopathy), joint pains, and headache and conjunctivitis lesions. During this incubation period, the patient is contagious typically for about one week before he/she develops a rash and for about one week thereafter. In children Rubella normally causes symptoms which last two days and include the following: rash beginning on the face which spreads to the rest of the body, low fever, posterior cervical lymphadenopathy (5). The swollen glands or lymph nodes can persist for up to a week and the fever rarely rises above 38°C the rash of German measles is typically pink or light red. The rash causes itching and often lasts for about three days. The rash disappears after a few days with no staining or peeling of the skin. When the rash clears up, the skin might shed in very small flakes where the rash covered it. Forchheimer's sign occurs in 20% of cases, and is characterized by small, red papules on the area of the soft palate. Other symptoms are swollen glands, coryza (cold like symptoms), and aching joints (especially in young women). Diagnosis is done through determination of Rubella virus specific IgM antibodies present in people recently infected by Rubella virus, but these antibodies can persist for over a year and a positive test result needs to be interpreted with caution. The presence of these antibodies along with, or a short time after, the characteristic rash confirms the diagnosis (5, 6). There is no specific treatment for Rubella.

CHICKENPOX

Chickenpox is an airborne disease which spreads easily through coughing or sneezing by ill individuals or through direct contact with secretions from the rash. Chickenpox is a highly contagious disease caused by a primary infection with varicella zoster virus (VZV). It usually starts with a vesicular skin rash mainly on

the body and head rather than on the limbs. The rash develops into itchy, raw pockmarks, which mostly heal without scarring (5, 7). On examination, the observer typically finds skin lesions at various stages of healing, and ulcers in the oral cavity and tonsil areas. The disease is most commonly observed in children. Children with chickenpox are infectious one to two days before the rash appears. They remain contagious until all lesions have crusted over (this takes approximately six days). Immunocompromised patients are contagious during the entire period as new lesions keep appearing. Crusted lesions are not contagious. Chickenpox is a highly contagious disease caused by primary infection with varicella zoster virus (VZV). It usually starts with a vesicular skin rash mainly on the body and head rather than on the limbs. The rash develops into itchy, raw pockmarks, which mostly heal without scarring. On examination, the observer typically finds skin lesions at various stages of healing, and ulcers in the oral cavity and tonsil areas. This is followed by the characteristic rash or oral sores, malaise, and a low-grade fever that signal the presence of the disease. Oral manifestations of the disease (enanthem) not uncommonly may precede the external rash (exanthema). In children the illness is not usually preceded by prodromal symptoms, and the first sign is the rash or the spots in the oral cavity. The rash begins as small red dots on the face, scalp, torso, upper arms and legs; progressing over 10–12 hours to small bumps, blisters and pustules; followed by umbilication and the formation of scabs (8).

At the blister stage, intense itching is usually present. Blisters may also occur on the palms, soles, and genital area. Commonly, visible evidence of the disease develops in the oral cavity and tonsil areas in the form of small ulcers which can be painful or itchy or both; this enanthem) can precede the exanthem by 1 to 3 days or can be concurrent. These symptoms of chickenpox appear 10 to 21 days after exposure to a contagious person. Because watery nasal discharge containing live virus usually precedes both exanthem (external rash) and enanthem (oral ulcers) by 1 to 2 days, the infected person actually becomes contagious one to two days prior to recognition of the disease. Contagiousness persists until all vesicular lesions have become dry crusts which usually entail four or five days, by which time nasal shedding of live virus also ceases. Chickenpox is rarely fatal, although it is generally more severe in adult men than in women or children. Non-immune pregnant women and those with a suppressed immune system are at highest risk of serious complications. The diagnosis of varicella is primarily clinical, with typical early "prodromal" symptoms, and then the characteristic rash and oral-cavity sores. Confirmation of the diagnosis can be sought through either examination of the fluid within the vesicles of the rash, or by testing blood for evidence of an acute immunologic response. Vesicular fluid can be examined with a Tzanck smear, or better by testing for direct fluorescent antibody. The fluid can also be "cultured", whereby attempts are made to grow the virus from a fluid sample.

SCARLET FEVER

Scarlet fever is an infectious disease of children. The disease itself is caused by secretion of pyrogenic exotoxins by the

infecting *Streptococcus*. Exotoxin A (*speA*) is probably the best studied of these toxins (9). Symptoms include sore throat, fever and a characteristic red rash. Scarlet fever is usually spread by inhalation. Scarlet fever is usually spread by the aerosol route (inhalation) but may also be spread by skin contact or by fomites. Asymptomatic carriage may occur in 15–20% of school-age children. The incubation period is 1–4 days. Scarlet fever is characterized by: fever, sore throat, bright red tongue with a "strawberry" appearance, Forchheimer spots (fleeting small, red spots on the soft palate). A characteristic rash, which is fine, red, and rough-textured, blanches upon pressure appears 12–72 hours after the fever starts generally begins on the chest and armpits and behind the ears. It may also appear in the groin on the face, often shows as red cheeks with a characteristic pale area around the mouth (circumoral pallor) is worse in the skin folds (so-called Pastia lines), where the rash runs together in the armpits and groin, appear and can persist after the rash is gone) may spread to cover the uvula begins to fade three to four days after onset and desquamation (peeling) begins. This phase begins with flakes peeling from the face. Peeling from the palms and around the fingers occurs about a week later. Peeling also occurs in the axilla, the groin, and the tips of fingers and toes. The rash is the most striking sign of scarlet fever. It usually appears first on the neck and face (often leaving a clear, unaffected area around the mouth). It looks like bad sunburn with tiny bumps, and it may itch. It then spreads to the chest and back and finally to the rest of the body. In the body creases, especially around the axillae (underarms) and elbows, the rash forms the classic red streaks known as Pastia lines. On very dark skin, the streaks may appear darker than the rest of the skin. Areas of rash usually turn white (or paler brown, with dark completed skin) when pressed on. By the sixth day of the infection, the rash usually fades, but the affected skin may begin to peel (5, 10).

Usually there are other symptoms that help to confirm a diagnosis of scarlet fever, including a reddened and sore throat, fever and swollen glands in the neck. Scarlet fever can also occur with a low fever. The tonsils and back of the throat may have a whitish coating, or appear red, swollen, and dotted with whitish or yellowish specks of pus. Early in the infection, the tongue may have a whitish or yellowish coating. Also, an infected person may have chills, body aches, nausea, vomiting, and loss of appetite.

When scarlet fever occurs because of a throat infection, the fever typically subsides within 3 to 5 days, and the sore throat passes soon afterward. The scarlet-fever rash usually fades on the sixth day after sore-throat symptoms started, and begins to peel (as described above). The infection itself is usually cured with a 10-day course of antibiotics, but it may take a few weeks for tonsils and swollen glands to return to normal. Scarlet fever can be diagnosed by clinical signs and symptoms. Complete blood count findings characteristic of Scarlet fever would show marked leukocytosis with neutrophil a and conserved or increased eosinophils, high erythrocyte sedimentation rate and C-reactive protein and elevation of antistreptolysin O titer. The treatment and course of scarlet fever are no

different from those of any strep throat-penicillin or macrolides.

Other diseases with febrile exanthema, but with a lower frequency, are epidemic megalerythema hand-foot-mouth disease, roseola infantum or the consequence of infection with different subtypes of enteroviruses or adenoviruses (11).

CONCLUSIONS

Any childhood febrile exanthema is a complex medical problem involving diagnostic challenges, epidemiological threats and a great concern for the parents and any physician, especially the infectious disease specialist, pediatrician or dermatologist should be prepared to face them.

ASPECTS OF PHYSICIAN – PATIENT COMMUNICATION IN THE PROGRAM OF SMOKING CESSATION (Abstract): The doctor-smoker patient communication is essential for smokers to realize the harmful effects of tobacco on health and the benefits of smoking cessation. Nicotine found in cigarettes is a powerful drug and a direct dependency generator, which makes smoking cessation difficult, the withdrawal syndrome being hard to overcome for many smokers. The doctor - smoker patient communication is a complex process of data, information and knowledge transmission, subjected to some semiotic rules. In the Counseling Center for Smoking Cessation (CCSC) from the Rehabilitation Clinical Hospital of Iasi the medical and psychological counseling and the pharmacologic therapy for smoking cessation is ensured by the qualified personnel. CCSC was founded in 2005, when the hospital was included in European Program: „European Network Smoke-Free Hospital", and experienced an important development in 2007 with the initiation "Stop Smoking" National Program of Ministry of Health. The doctor - smoker patient communication in the CCSC was conducted during the smoker's recruitment, therapeutic and post therapeutic period, a special place being occupied by the doctor - medical staff communication, including smoker medical students. The number of people who became nonsmokers after being counseled at our center was the evidence of the effectiveness of this communication. The obtained results determined us to join the global fight against smoking and to propose the introduction of the smoking cessation program in the curriculum of the medical education institutions. **Keywords:** DOCTOR - PATIENT COMMUNICATION, SMOKING, CESSATION.

ISRA Center Marketing Research conducted a study in 2007 for the Pfizer Romania Pharmaceutical Company which aimed to evaluate the incidence of tobacco use and the assessment of smoking behavior in Romania. This study showed that among the 3326 people aged over 18, 1550 were smokers, the incidence being higher for males. Of

these, 43.9% said that they thought to quit smoking. Geographically, in Muntenia the percentage of smokers was 51%, 49.7% in Moldova, 40.1% in Bucharest and 42.4% in Banat. Being asked: "Is it possible to have health problems due to smoking?", the majority answered: "Yes!" (1).

Because the incidence and prevalence of smoking increases from year to year, a worrying phenomenon also in Romania, as shown in the above study, in the same year - 2007, the Ministry of Health initiated The National Program "Stop Smoking", which provides medical and psychological counseling and therapy for smoking cessation.

Smoking refers to the consumption of tobacco in form of cigarettes and it is a habit voluntarily acquired and which causes addiction. During the "Stop Smoking" program, there were established counseling and therapy centers for smoking cessation across the country, which were coordinated by pulmonologists with special training regarding the counseling of smokers, one of these being in Rehabilitation Clinical Hospital from Iasi (2).

Of the over 4,800 toxic substances existing in cigarette smoke, nicotine is the one that causes addiction, which is classified by The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) (3) and Fifth Edition (DSM-5) (4) as a disease. According to this authority, the criteria for this diagnosis include at least three of these phenomena during the last year to a smoker:

- Smoking more intense than normal;
- Strong desire to smoke, despite all efforts to reduce the number of cigarettes smoked per day;
- Tolerance to nicotine, manifested by the reduction of its effect and the need of increasing the number of cigarettes to achieve the same effect;
- Withdrawal symptoms after discontinuing smoking;
- Increase time spent smoking and acquiring cigarette, giving up the participation to different social or educational activities;
- Continue smoking despite the danger of ill health awareness.

The nicotinic withdrawal is also classified as a disease induced by nicotine consumption, according to DSM-IV-TR and DSM-5. It occurs in some people with major symptoms in the early days: very strong desire to smoke, difficulty concentrating, headache, nervousness, insomnia, irritability and even depression, increased appetite, reduced heart rate. These symptoms may disappear within a month.

Smoking is responsible worldwide for more than 85% of all deaths due to lung cancer, being the major cause of emphysema, bronchitis, Chronic Obstructive Pulmonary Disease (COPD) and cardiovascular diseases. Tobacco may also determine neoplasms located in the oral cavity, esophagus, pancreas, stomach, larynx, it can complicate surgery recovery, delay healing of wounds and fractures, decrease bone density, causing osteoporosis and it can affect the excretory and genital systems, skin and mucous membranes etc. (5, 6, 7, 8).

Counseling for smoking cessation has major and immediate health benefits, regardless the smoker’s age. This medical counseling requires meetings and discussions where the physician explains to the patient the harmful effects of smoking on health and its negative economic consequences. Some smokers want to quit smoking but can not do it alone. In the "Stop Smoking" National Program of the Minis-

try of Health, after the counseling session conducted by the specialist doctor, patients who wanted to be included in the program have returned and attended medical and psychological counseling provided by the physician and psychologist and pharmacological therapy.

Drug treatment was made with Bupropion and Varenicline for 2-3 months. This treatment helps the smoker to overcome the withdrawal syndrome by the action of drugs on the central nervous system, inhibiting the wish to smoke. After the initial consultation, follows a period of 2 weeks of treatment then the patient went to the consultation to assess efficacy, followed by another period of treatment, until 2 or 3 months, depending on the drug used. After completing this treatment, the patient is monitored for another 6 months. The patient-medical specialist meetings involve direct communication.

The medical specialist- patient communication

In the entire world, the interpersonal communication is located to the top of communication hierarchy. It is a complex process of transmission of information, data and knowledge from one source to another, connecting individuals, communities, groups, companies, ensuring cooperation and collaboration between them.

The doctor-patient communication represents a social interaction which implies the existence of the two partners, one being the emitter (source message), and the other being the receiver (target message). Both partners have a common set of signs and they follow a common set of semiotic rules.

These semiotic rules are classified into three categories:

1. Syntactic - defines the formal properties of signs and symbols;

2. Pragmatic - concerns the relations between signs, expressions and their uses;

3. Semantic - reflects interactions between symbols and signs and their meanings (9).

Interpersonal communication is examined and analyzed according to several possible classifications. After the channel used, communication can be: auditory, olfactory, visual, tactile. Another classification is: verbal (words are vehicles for information) and non-verbal (physical methods are vehicles for information: signs and body language, paralanguage, eye contact, touching etc.).

Communication can be written (letters, recommendations, reports, statements etc.) or oral (discussion, exposure).

After the means used in the transmission of information, communication can be realised through: auditory media (radio, teleconferences), print media (newspapers), audiovisual media (television), and electronic media (e-mail, audio and video files).

Considering communication conditions, it can be: face to face (when all the four senses are involved) or remote communication (involving hearing, sight, or both) (10).

General aspects of the physician-patient relationship

The chronic respiratory pathology that dominates the daily hospital activity has brought us face to face with the consequences of smoking, due to the patients suffering from COPD, chronic bronchitis and pulmonary emphysema. The communication with these smoking patients is present in the daily activity, but even more within the anti-smoking program at the Rehabilitation Clinical Hospital from Iasi.

The communicational component is a process that needs abilities in the interpersonal relationships: listening, asking, speaking, analysis and evaluation. These partially native skills need to be shaped by a specific education and also on the basis of the personal experiences, as the ability of advising is acquired in time.

"Stop Smoking" the National Program cannot take place without the addressability of people, which has risen up from zero to a high number of smokers who have asked for help in giving up smoking. The first measure of the plan was to inform people in Iasi about the existence of this program, to present them the facilities of it and also to tell them about this Counseling Center for Smoking Cessation within the Rehabilitation Clinical Hospital. This Center was founded in 2005, when the hospital was included in European Program: „European Network Smoke-Free Hospital", and experienced an important development in 2007 with the initiation "Stop Smoking" National Program of Ministry of Health. We used therefore all the available means of communication, ranging from inpatients, hospital staff and students, to written press, radio and television. The second main element was the message itself which was delivered to people in order to encourage them to contact the counseling center. Giving up smoking is possible, encouraging smokers and their entourage to take action, supplying all the details on how to apply for the services of the counseling center. In all of this, a balance was made between the positive and negative features of the message.

We tried to change the vision of smokers and non-smokers, convincing smokers to be more responsible towards their own health and of the people around them and the nonsmokers to convince the smokers to give up this habit. The main point of the message was that immediate action is urged because it is possible to give up smoking, being possible for the health status to be recovered. All the details were previously debated with the media representatives, all the aspects concerning the communication being paid attention, even to the apparently minor ones. When the message was delivered audio-visually, the aspects regarding the posture, voice, audio-visual amplification were carefully analyzed. During the radio and television broadcasts, the persons showing interest could interact with us live and that were advised to address to our center. Each time possible, the interaction with the audience was ensured, avoiding as much as possible the speeches. The message was insistently repeated using as much as possible present tense and imperative verbs.

The written press was used to underline the consequences on morbidity and mortality of the diseases caused by the active and passive smoking. These consequences equally affect both the men and women and depend on the number of cigarettes smoked per day, age and moment of start. The message was spread presenting advantages of giving up smoking on short and long periods, urging immediate action in giving up. Messages that underlined the negative aspects of smoking and the positive ones of giving up, confessions of the ex-smokers were used for the inpatients and the smokers in the hospital's staff, emphasizing the possibility of direct addressing to the center. The inpatients with chronic addiction had two different attitudes after discussing with the physician. Some of them requested help in giving up smoking, some others had no reaction. For the smoking in patients who did not request out help, we initiated

the minimal advice - three minutes intervention, which is the most efficacious prevention action. The chances to succeed are bigger if the patient attends the counseling center compared to trying to give up by them. We avoided mentioning percents and we used assertions such as: 'A smoker dies each 5 minutes!' or 'Give up smoking gives years to the life and life to the years'. If the medical staff would give the *three minutes intervention minimal advice* to each smoker, 2200 years of life every 1 million people would be saved each year by preventing the occurrence of diseases caused by smoking (11). Psychologically, the nonsmoking staff is more credible than the smoking one. Mass-media gave us the chance to implement educational programs which advised the nonsmokers not to take up smoking and the smokers to give up by applying to the anti-smoking counseling center within the Rehabilitation Clinical Hospital from Iasi. It is important to mention that the smokers usually tend to ignore the danger in which they put people around them, who are passive smokers- having the same risks. The process of counseling is possible, useful and needs to take place gradually.

The physician-smoker patient communication during the therapeutic period

The therapeutic period starts at the moment when the patient comes to the counseling center for giving up smoking, admitting that he wants to give up, this representing the first step in the therapeutic success. At this moment, the communication between the physician and the patient has a special meaning, within the process of giving up smoking. The first step when communication is initiated is to explain to the patient the path that needs to be followed, were the nicotine withdrawal syndrome is very important. This syndrome is defined by the totality of symptoms which occur when cutting off the intake of nicotine after a prolonged period of use. It is given a special attention to it in order to realize that giving up is difficult and in order to recognize it and in this way to avoid panic. Therefore, the appointments in the first period are frequent, asking the smokers to contact us each time the fear occurs. At this moment, the communication with the smokers and their relatives takes place in all the four situations earlier mentioned:

- one emitter and one receptor: face to face communication with the patient during the session;
- one emitter and more receptors: the communication with the smoker and his relatives or a group of smokers, during the first session;
- more emitters and one receptor: medical counseling followed by the psychologically one, both given by a specialized person;
- more emitters and more receptors: the public presentations with supportive and educational role (8, 10, 11).

The style of communication is influenced by the personal sensitivity and the persuasion skills of the person who gives the message, each physician having a particular style of interaction with patients, shaped up by instruction, exercise and experience. The persuasion capacity of the physician is revealed by his ability to ask questions and make affirmations in the moment of interaction with the patient, while the personal sensitivity represents the degree of the control over expressing his emotions. Four personal communication styles are known to influence the quality of

physician-patient relationship: analytical, respectful, expressive, and directive. The difficult relationships may occur between the persons who belong to the analytical-expressive and respectful-directive styles. The verbal and nonverbal communication between the physician and the smoker has different percents, depending on the emitter and the receptor, the verbal component - 7-10%, the vocal one (clarity, inflexion, speaking speed and firmness) - 35-38% and the visual one (mimics and acts, visual contact) - 55%, being the most representative (10, 11).

Communication between transmitter and receiver can be disrupted by psychological, social, structural or environmental barriers that are technically called "noise". This can create a situation in which the transmitter and receiver do not see the same meaning of the message. To check the reception of the message by the patient, the medical provider uses different opened questions that let the liberty of several response options (example: What you did not understand?).

In the process of communication with the smokers I assured a persuasive communication, so that the smoker listens to the message, accepts it and implements it. Once the smoker knows how dangerous smoking is and tries to abandon tobacco, usually problems occur due to psychological dependence because smoking cessation causes numerous demotivating issues such as weight gain, withdrawal symptoms, sudden desire to smoke, depression, insomnia.

Therefore addiction requires medical treatment that consists of two essential components: the behavior intervention (education, information, advice) and the pharmacological support (treatment of the withdrawal syndrome), medical intervention increasing the success rate.

Stages of smoking cessation were formalized by British researchers in the 5 A:

- ASK (ask the subject if he is a smoker to force him to admit their status)
- ADVISE (advising to quit smoking)
- ASSESS (evaluation of the desire to give up smoking)
- ASSIST (help him to make an attempt to quit smoking)
- ARRANGE (maintaining constant contact for support)

For the smokers with compliance issues we can apply to the 5 R in persuasive form:

- RELEVANCE (personalized information)
- RISKS (both for the smokers and their entourage)
- REWARDS (smoking cessation benefits)
- ROADBLOCKS (obstacles that may arise)
- REPETITION (repeating information)

Non-pharmacological therapy is based on social support during and after treatment. Educational practice includes: educational models (social interaction, the processing of information, personal preferences, and behavioral system), educational strategies (direct, indirect and interactive training, personal documentation), educational methods and educational materials (texts, pictures, posters, multimedia interactions) (10, 11).

All problems encountered were analyzed and continuously improved over these 7 years of activity in this field.

Specifics of doctor-patient communication in the post-therapeutic period

In post-treatment period we should keep in touch and to ensure free addressability when the patient feels the need to discuss

with us. Doctor-patient relationship is a key component of a good clinical practice in any situation, including the anti-tobacco treatment throughout its duration, but also in post-treatment period in order to consolidate the success and avoid relapse. The pre- and post-therapy counseling depends entirely on the doctor-patient relationship, the patient's level of participation and the patient's satisfaction.

Practical experience has put us in front of all situations regarding possible types of patient-physician relationship. There are 3 well-known views of the physician-patient relationship: as a consensual event – Parson model (1951) (12), Szasz and Hollender model (1956) (13), Stewart and Roter model (1989) (14), as a conflict event - model Freidson (1971), or as a process of negotiation.

Because the patient goes to the counseling center on his own initiative or on the entourage's initiative, we try to take control using the types of relationships based on the degree of control identified by Stewart and Roter (1989):

• Paternalistic (doctor-centered relationship; use of closed questions; model focused on defining illness and diagnosis).

• Consumerist (patient-centered relationship; he knows exactly what he wants).

• Absent (in this case focusing on patient fails; the doctor abandons the control of the patient, he is not willing to accept the doctor; the final result is a stalemate).

• Reciprocity (using open questions, encouraging the patient to talk about his suffering) (14).

These theoretical models concern the physician-patient relationship in terms of consensus, being static models, but in practice the relationship has a dynamic character due to problems occurring during the treatment and post-treatment. The situation is maintained even after exiting the program as any event can cause a relapse and long-term failure, if abandoning tobacco was not consolidated as a habit.

The dynamic nature of the doctor-patient relationship considered in the conflict and negotiation models, and the many reasons that can damage the communication, put us in the position to decide whether or not we continue the treatment, so that we can take a decision regarding the patient, approaching problems directly and identifying under what circumstances the partnership can continue.

Particularities regarding the communication doctor-medical staff, including medical students

Practical activity in the anti-smoking counseling center has made us confront with different issues regarding the medical staff of the hospital, various medical units and students from "Grigore T. Popa" University of Medicine and Pharmacy, Iasi (15).

The habit of smoking on healthcare professionals has an influence on their professional credibility and effectiveness in tobacco control activities. Studies shown that non-smoking male doctors advise patients more frequently to quit smoking, than the male doctors that smoke. The negative attitude of the latter affect the success of their therapeutic practices. For women doctors, differences are less significant between smokers and nonsmokers. Smoker healthcare professionals, as well as medical students, are a special target group because they can provide an assessment of the effectiveness of anti-smoking counseling program (16).

Based on the initiatives taken by the National Institute of Cancer of including

the anti-smoking education programs in the American medical education institutions (17), we considered healthcare professionals a very important target group and we proposed, along with other colleagues involved in"Stop Smoking" National Program, to also include in the Romanian medical education institutions, training classes about the harmful effects of smoking and smoking cessation treatment modalities.

NEUROENDOCRINE TUMORS: CHOOSING APPROPRIATE IMAGING METHODS (Abstract): With an overall increased incidence in general population neuroendocrine tumors (NETs) are often late diagnosed. Symptoms are nonspecific and almost 50% of all patients have regional or distant metastases at the time of diagnosis. This article provides an overview of the current state of the imaging modalities used for primary tumor visualization, staging and follow-up. Detection of NETs and patient monitoring relies mainly on anatomical imaging such as computed tomography (CT), magnetic resonance imaging (MRI), and ultrasonography (US) under certain conditions. Molecular imaging techniques in combination with CT or MRI (hybrid imaging) greatly benefit patient management, including better localization of occult tumors and better staging. Octreoscan or somatostatin receptors (SSTRs) scintigraphic imaging in combination with CT represents the standard diagnostic of NETs in most countries. However, it is rapidly surpassed by SSTRs PET/CT with 68Ga-labelled somatostatin analogues with a superior spatial resolution and faster imaging (one-stop shop principle). Other more specific tracers are 18F-L-DOPA, 11C-L-DOPA and 11C-5-hydroxytryptophan, which have demonstrated excellent results in previously published studies. Diagnosis of patients with NETs is a complex process and, it is unlikely that any single diagnostic modality to be effective. Thus, NET diagnosis is a process utilizing a variety of methods including blood, urine and tumor tissue samples in combination with anatomical or hybrid imaging for localization, delineation and staging of the disease. Diagnostic approach to patients with NETs should focus on including hybrid imaging methods, which might play an important role in the future. **Keywords:** NEUROENDOCRINE TUMORS, ANATOMIC IMAGING, FUNCTIONAL IMAGING.

Neuroendocrine tumors (NETs) include a variety of malignancies that can arise from neuroendocrine cells throughout the body. They can store and secrete different peptides and neuroamines that cause characteristic hormonal syndromes, often late diagnosed (1, 2). Nonspecific symptoms are characteristic to the disease, and almost 50% of all patients have regional or distant metastases at the time of diagnosis (3). NETs can arise in many different areas of the body and are most often localized in the gastrointestinal tract (70%) and the bronchopulmonary system (25%), with substantial variations in both clinical presentation and tumor biology. NETs are mainly spo-

radic but may occur in a familial context of autosomal dominant inherited syndromes such as MEN1, MEN2, Von Hippel-Lindau disease, neurofibromatosis type 1 and multiple tuberous sclerosis. The annual incidence of clinically significant neuroendocrine tumors is approximately 2.5-5 per 100,000 (4, 5).

Anatomic imaging. *Ultrasonography* (US) is frequently used in the evaluation of gastroenteropancreatic neuroendocrine tumors (GEP-NETs), with a low success rate, between 13–27%. It is valuable for the localization of pancreatic and liver metastases and particularly in the preoperative assessment of patients (fig. 1).

Endoscopic US (EUS) could be an excellent imaging modality to detect pancreatic NETs, with pooled sensitivity and specificity of 87 and 98%, respectively. US performed intraoperatively combined with intraoperative palpation could raise the sensitivity up to 91% (6).

Computed tomography (CT) is the most commonly used technique for primary tumor localization, staging, therapeutic monitoring, and follow-up of patients with NETs. Triple-phase intravenous contrast-enhanced CT (early arterial, portal-venous, and equilibrium) is usually performed (fig. 2). In primary NETs, the average sensitivity of a CT scan is 73%. A better sensitivity of 80% in detecting NET metastases is reached for liver metastases and 75% sensitivity for extrahepatic metastases (7).

Magnetic resonance imaging (MRI) findings provide a broad spectrum of information for both primary and metastatic tumors. On non-contrast MRI they can be hypointense or isointense on T1-weighted images. Metastases to the liver are typically hyperintense on T2-weighted images. A primary tumor is best identified on dynamic gadolinium contrast images (fig. 3).MRI may be superior to CT regarding liver lesion characterization but may not be as useful in the identification and follow-up of extrahepatic disease (13). A study comparing MRI, CT and standard somatostatin receptor scintigraphy (SSR) reported 95.2% sensitivity for MRI, 78.5% sensitivity for CT and 49.3% sensitivity for the OctreoScan in detecting hepatic metastases (8, 9).

Functional imaging. These techniques depict the somatostatin receptor status, metabolic activity, or specific amine or peptide regulatory profile. The human somatostatin receptor family consists of 5 subtypes each differentially distributed throughout the body (SST1-SST5).

The radiolabeled somatostatin analogue (SSA) 111 In-pentetreotide is the most commonly used agent in somatostatin receptor scintigraphy. The tracer is commercially available as 111In-DTPA-D-Phe1-octreotide (Octreoscan, Mallinckrodt Medical, St. Louis, MO, USA) and used for scintigraphic localization of primary and metastatic neuroendocrine tumors that express somatostatin receptors subtype 2 and 5 (fig. 4) (10).

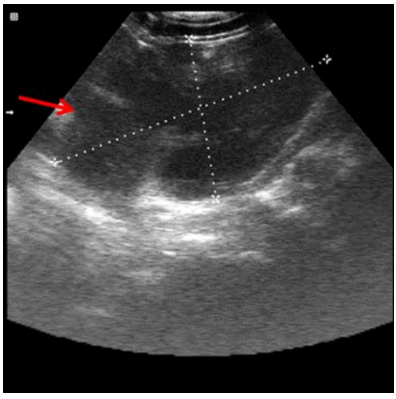

Fig. 1. Nonfunctional pancreatic neuroendocrine tumor

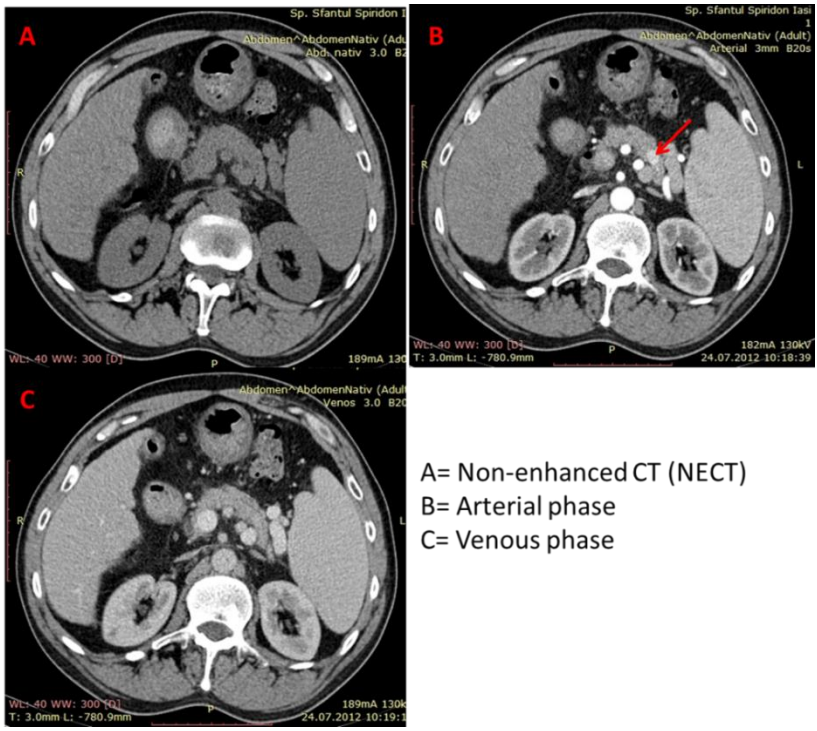

Fig. 2. Computed tomography of insulinoma of the pancreas. Typically, insulinomas are hyper vascular (arrow) and demonstrate more enhancement than normal pancreatic parenchyma during the arterial phase.

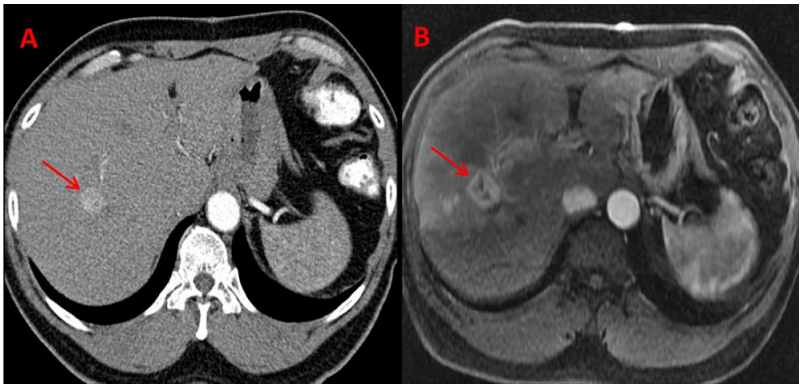

Fig. 3. Liver metastases from a neuroendocrine tumor (arrows) CT (A) versus MRI (B). The hyper vascular liver metastases are more clearly observed on the T1w gadolinium enhanced MRI (B) compared to the arterial phase CT (A).

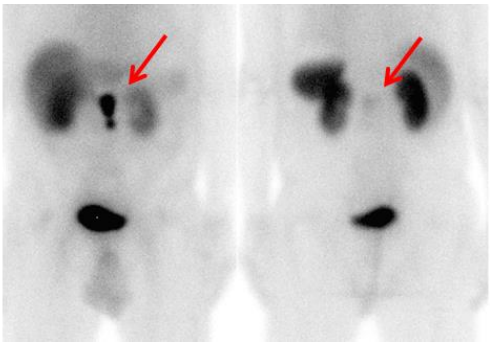

Fig. 4. Octreotide (111 In-pentetreotide) anterior and posterior images obtained at 24 hours. Increased activity is depicted in the pancreatic region corresponding to a neuroendocrine carcinoma. No distant metastases were visualized.

Alternatively, iodine metaiodobenzylguanidine (^{131}I /^{123}I MIBG) scintigraphy is an imaging test that confirms the presence of and monitors primary or metastatic pheochromocytoma (PCC) and paragangliomas (PGLs), and certain other NETs (neuroblastoma) (fig. 5).

False-negative results could occur with extra-adrenal tumors. Several drugs, such as opioids, tricyclic antidepressants, and antihypertensive drugs like labetalol can also affect MIBG uptake, leading to less intense or false-negative scans. MIBG scintigraphy performs poorly for head and neck PGLs and may also miss metastatic disease. ^{131}I MIBG imaging is performed after 24 hours, 48 hours and, if necessary, at 72 hours; only planar views are obtained. ^{123}I MIBG scintigraphy is performed after 24 hours and, if necessary, at 48 hours; single-photon emission computed tomography (SPECT) can be performed (11).

Hybrid imaging. *F-18 FDG PET/CT.* Positron emission tomography (PET) together with CT, using ^{18}F-fluorodeoxyglucose (FDG PET/CT) has limited usefulness in NETs due to their low metabolic activity. 18F-FDG PET/CT may instead be considered for imaging of high-grade NETs (poorly-differentiated), where the relationship between standardized uptake value (SUV) and overall survival can provide predictive information regarding overall survival and progression (fig. 6) (12).

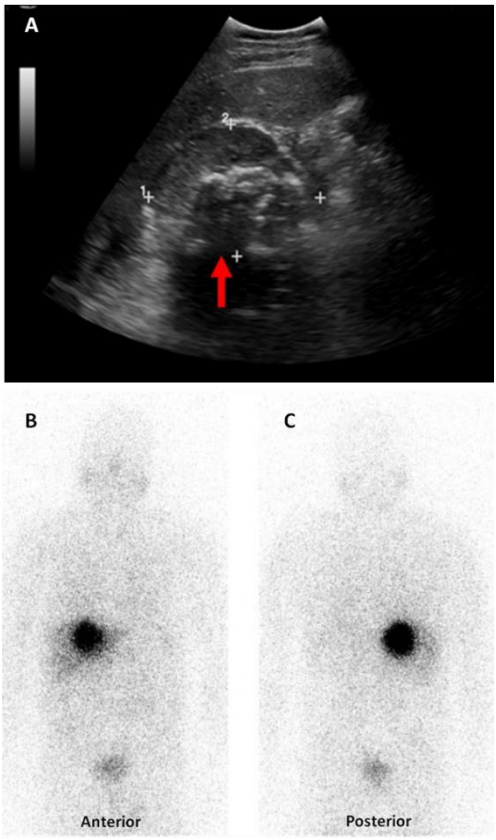

Fig. 5. Pheochromocytoma: US reveals a large echogenic lesion with calcifications on the right adrenal gland (arrow) (A). 131 I-MIBG scan shows a dark sphere (B, C).

18F-DOPA PET/CT. 18F-DOPA (L-3, 4-dihydroxy-6-18F-fluorophenylalanine), fluorodopa (FDOPA) is a tracer which depicts catecholamine metabolism and

exhibits an intense concentration in NETs, independent of somatostatin receptor. The main indication for FDOPA may be for the patients with insulinoma or paraganglioma. The reported sensitivity and specificity rates of [18F] DOPA PET or PET/CT for the diagnosis of thoracic and gastroenteropancreatic NETs were 77% and 95%, respectively (13). In patients with pheochromocytoma or paraganglioma the rates were 92% (sensitivity) and 92% (specificity), respectively.

PET/CT Imaging with Somatostatin Analogs. The introduction of somatostatin receptor PET/CT, somatostatin analogs (SSA) labeled with gallium-68 (Ga-68-DOTA-peptides) has allowed an accurate imaging of SSTRs by PET. DOTA peptide PET/CT has a significant role in the staging of well-differentiated gastroenteropancreatic tumors. It is recommended for clinical use in the initial diagnosis and for the evaluation of tumor response. The overall sensitivity of 68Ga-SSA-PET/CT for NETs is >90%, while the specificity ranges from 92 to 98%.The clinical impact of differences in SSTR binding affinity has not been proven, and therefore no preferential use of one compound over the others can be advised (14).

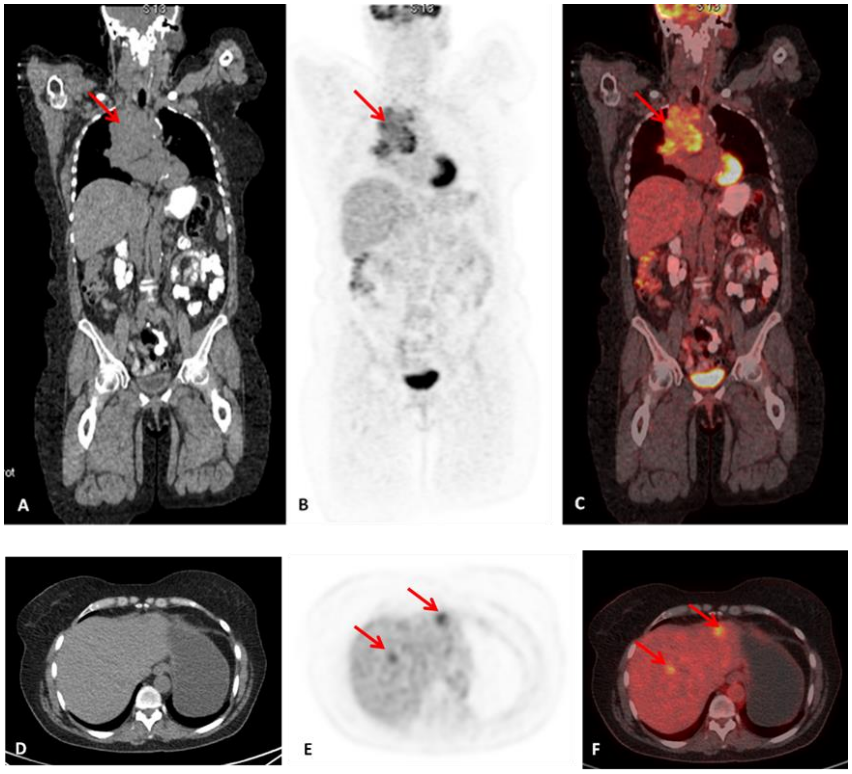

Fig. 6. Upper row: Patient with bronchopulmonary carcinoid, Ki-67 30-40%. Positive FDG PET uptake at the tumor level (B, arrow).
Bottom row: Liver metastases from a neuroendocrine tumor of midgut origin, Ki 67 10%. Faint FDG uptake (maximum SUV, 2.5 and 2.9 g/ml, E, arrows).

Future techniques. Other investigational tracers include ^{18}F-labeled amine, ^{18}F-fluorothymidine (FLT) and ^{11}C-labeled precursors, such as levodopa and serotonin, but the clinical experience is still limited (27).

There is great interest in the emergence of the so-called pan-receptor somatostatin analogs. Pasireotide (SOM230) is a novel multi receptor-targeted somatostatin analog with high binding affinity for SST receptor subtypes 1, 2, 3, and 5.

CONCLUSIONS

Our overview suggests that a single diagnostic test will not be effective to assess the NETs. The diagnosis will use a variety of methods including blood and urine tests and tumor biopsy in combination with anatomical and molecular imaging for localization, delineation, and staging of the disease, as the basis for optimal selection of therapy.

Future advances in NET diagnosis need to consider two realities. Firstly, the proper approach focused on validation of the present techniques. Secondly, a long-term strategy to develop a multilevel integration scheme of biologic and genomic diagnosis to provide added value to the imaging techniques. Thus, a fusion product of molecular and genomic information with tumor imaging is likely to be the essence of future NET diagnosis.

CARDIOTOXICITY OF LEVOFLOXACIN AND CIPROFLOXACIN

Fluoroquinolones are a class of antibiotics widely used in the treatment of common bacterial infections and are unusual because they are synthesized, not isolated from living organisms. One potentially serious adverse effect is prolongation of QT interval that may lead to *torsades de pointes* or ventricular arrhythmias. A group of researchers did a study on animals using Wistar albino rats .The study was divided into two experiments to determin the effects of levofloxacin and ciprofloxacin on rats with acute myocardial dysfunction (AMI) induced by isoproterenol (sixty rats into five groups of twelve rats each) and rats without AMI (twenty five rats into five groups of five rats each). They analised the changes in ECG pattern, the serum level of cardiac enzymes and the histopathologic features in the myocardium. In rats without AMI, the ECG pattern and the heart beats were normal but the rats with MI presented an abnormal pattern with specific change in ST segment and abnormal Q waves. The level of lactate dehydrogenase was increased in both experiments. The creatine kinase-MB activity was increased compared to the saline controls, however in the MI experiment treatment with any dose of levofloxacin or large dose of ciprofloxacin (300 mg/kg) the CK-MB activity was significantly increased. The histopathologic findings in cardiac sections, stained with hematoxylin and eosin, revealed different degrees of inflammatory cell infiltration, cardiomyocyte degeneration, intermuscular edema, loss of the cardiac striations and hemorrhage as an effect of levofloxacin and ciprofloxacin. The conclusion of the study was that it is important to monitor patients with a history of cardiac disease requiring treatment with these antibiotics (Ahmed M. Abdelradya, Sawsan A. Zaitoneb, Noha E. Faragd, et al. Cardiotoxic effect of levofloxacin and ciprofloxacin in rats with/without acute myocardial infarction: Impact on cardiac rhythm and cardiac expression of Kv4.3, Kv1.2 and Nav1.5 channels. *Biomedicine & Pharmacotherapy* 2017; 92: 196-206).

ALCOHOLIC LIVER DISEASE - EPIDEMIOLOGY AND RISK FACTORS (Abstract): Alcoholic liver disease (ALD) accounts for the majority of chronic liver diseases in Occidental countries and remains a major cause of liver-related mortality in worldwide. The spectrum of ALD includes steatosis in patients which consume over 80g of alcohol per day, alcoholic steatohepatitis and liver cirrhosis in approximately 15% of patients. Once cirrhosis is established, the annual risk for hepatocellular carcinoma is about 1–2%. Environmental factors such as drinking patterns, coexisting liver disease, obesity, diet and co-medication may affect the natural course of ALD. Abstinence is the hallmark of therapy for ALD, and nutritional therapy is the first line in therapeutical intervention. **Keywords:** ALCOHOLIC LIVER DISEASE, ALCOHOL CONSUMPTION, ENVIRONMENTAL FACTORS, ABSTINENCE

DEFINITION

Alcoholic liver disease (ALD) covers a large spectrum of structural and functional hepatic modifications, from benign and frequent forms (asymptomatic hepatomegaly) to the most severe ones (acute liver failure), modifications that share the same etiologic factor: systematic and long term consumption of alcoholic beverages (1-3). The spectrum of clinical manifestations and hepatic morfopathological modifications varies widely: from liver steatosis (alcoholic fatty liver) to inflammatory and necrotic lesions (alcoholic hepatitis), progressive fibrosis (hepatic cirrhosis) (4, 5, 6).

EPIDEMIOLOGY

ALD is probably one of the oldest forms of manifestation in chronic liver disease, considering that fermented alcoholic beverages have been consumed for hundreds of years, ever since the Neolithic Period (7, 8).

After 1970, many countries registered a fall in mortality by ALD; unfortunately, during the last decade, we have witnessed an increase in the incidence of this condition, and, implicitly in mortality, reaching 14.3/100,000 in France and 7.9/100,000 in the United States (9).

A lot of information concerning incidence, risk factors and ALD evolution are outdated, as while analyzing existing literature, we can easily see that most studies were carried out 15 or 20 years ago.

The real incidence and prevalence of ALD are difficult to evaluate, as many cases are asymptomatic, remaining thus

undiagnosed and unreported. On a group of 1,604 patients with chronic alcohol consumption which underwent liver biopsy, in 20% of them morfopathological modifications in alcoholic hepatitis have been registered (10). Other studies estimate alcoholic hepatitis incidence in 10-35% of chronic alcohol consumers.

Although alcohol consumption is increasing, numbers related to mortality by ALD remained constant in the last 24 years, the United States even witnessing a reduction from 6.9/100,000 inhabitants in 1980, to 4.4%/100,000 in 2003 (11, 12).

Mortality by ALD mainly depends on the severity of hepatic affectation, varying from 20% in light forms, to 30-60% in cases of severe alcoholic hepatitis (13). Acute hepatitis has the highest mortality rate, over 15% within 30 days and up to 39% within 1-year follow up (14,15). Great Britain is one of the countries where mortality by chronic liver disease has raised dramatically in the course of a few decades (1979-2005), the main cause of death by hepatic affectation being ALD. In this area, mortality by ALD has jumped from 1.7 to 10.4/100,000 in men, and from 0.9 to 5.0/100,000 in women with alcoholic hepatitis, the increasing trend in alcohol consumption and mortality among young people aged between 25 and 34 years causing concerns (16).

On the long term, survival in patients with uncomplicated alcoholic hepatitis reaches 58%, and only 35% in patients with alcoholic hepatitis developed on cirrhotic background (17).

ALD patients who continue to consume alcohol have a reserved prognosis on the short term as well as on the long term: 5-year survival in compensated cirrhosis is almost 90% in abstinent and drops below 70% in those who continue to drink, while the occurrence of decompensation indicates a chance of survival under 30% (18).

A study carried performed on a group of patients with alcoholic hepatitis fallowed up during 5 years through annually evaluations by liver biopsy has shown the occurrence of cirrhotic morfopathological modifications in almost 40% of them (19), as well as the possibility that resolution of histological modifications be complete in 10% of abstinent (20). Regrettably, in many abstinent it can be noticed a certain progression towards liver cirrhosis, while women, even in conditions of total abstinence, seem to be more exposed to an aggravation of lesions.

In an earlier study, Bird specifies that the risk of developing hepatic cirrhosis in patients with alcoholic hepatitis is 10-20% every year, and in the end, over 70% of them, in time, develop cirrhosis with all its complications (21).

ALD occurrence is influenced by many factors, mainly alcohol consumption, thus geographic distribution and prevalence of the disease correlate with distribution of alcohol consumption.

ALCOHOL CONSUMPTION – A SOCIAL PROBLEM

Excessive alcohol consumption implies high economic and social costs. Alcohol accounts for 1.8 million deaths worldwide, while in Europe, alcohol consumption is responsible for more than 55,000 deaths amongst those aged between 15 and 29. In the United States, alcoholism prevalence is 20% in hospitalized adults (22). In Great Britain, 1 in 3 patients assisted through primary care services has an alcohol addiction.

ALD incidence is strongly correlated with geographic distribution of alcohol consumption. According to a recent WHO

report (*Global Status Report on Alcohol and Health*), published in 2011, alcohol consumption is a major global health issue (23). The WHO report estimates that 4% of deaths worldwide are caused by excessive alcohol drinking, totalizing more deaths than AIDS, tuberculosis or violence (24). Alcohol consumption is considered to be the most important risk factor leading to death in men aged between 15 and 59.

The lowest mortality rate determined by alcohol-induced pathology is registered in regions with Islamic population, where alcohol consumption is reduced; in Western Europe also mortality is relatively low (in comparison with the East), although numbers referring to alcohol consumption are significant.

Globally, pathology determined by alcohol consumption accounts for 6.2% of registered deaths in males, beside 1.1% in females. Damaging alcohol drinking is fatal especially in youngsters.

Annually, 320,000 young people (15-29 years of age) worldwide die from alcohol consumption related causes, accounting for 9% of the total number of deaths at this age.

Quantity of alcohol consumed

The largest quantity of alcohol is consumed in developed countries. Although Western European countries report an important consumption of alcohol, alcohol induced mortality is significantly lower (while morbidity rate is considerable), as opposed to Eastern countries with the highest levels of alcohol consumption, and, probably, it is the type of beverages and consumption that determine much higher morbidity and mortality rates (9).

Alcohol drinking is largely spread, numbers are in some areas alarming, but a considerable percentage of the population is totally abstinent: almost half of men and over 2/3 of women have not drunk alcohol at all in the last years. From the point of view of the geographic distribution, populations in North African and South Asian regions are the most abstinent - areas with Muslim inhabitants, where alcohol is forbidden by religion.

In 2005, worldwide, the level of consumption of pure alcohol per inhabitant (persons over 15 years of age) was 6.13 liters. This largely varies geographically: developed countries, especially from the Northern hemisphere, report the highest values, but so do Argentina, Australia and New Zeeland. South African, South and North American countries register a moderate level of consumption, while the North African and Sub Saharian, East Mediterranean and South-East Asia regions show reduced levels of alcohol drinking (23).

It must be underlined that an important percentage (28.6%) of this consumption, the equivalent of 1.76 liters, is represented by unregistered alcohol (homemade, produced in illegal conditions or sold without taxes (23). Consumption of illegal beverages is much more dangerous (to the hepatic toxic effect of alcohol that of noxious substances is added as well as the impurities contained by these inappropriately produced beverages).

Alcohol drinking in Eastern European countries exceeds the European average level, in Russia and the Community of Independent States (CIS) every fifth death is caused by excessive drinking. According to the WHO report, Romania is among the countries with the highest alcohol drinking levels in Europe: the national average is 15.3 liters/inhabitant compared to 12.2 liters, which is the EU average; we exceed by far the European average, while the ex-Soviet states are ahead of us.

Type of alcohol

Worldwide, spirits are the most consumed beverages: over 45% of the total quantity of alcohol consumed (23). However, as there are geographical differences in quantities consumed, so are in types of drinks: beer, wine, spirits etc.

Traditionally, in Europe there were marked differences concerning preferences: it was well known that Nordic countries preferred beer, while the South-East consumed mostly wine; at present, these practices tend to change (35). Spirits are consumed mostly in Asia and Eastern Europe, whereas wine tops the preferences list of South Americans, as well as of some European states. Beer is one of the most favorite alcoholic drinks, being consumed by most Westerns countries, Northern Europe, Australia and most Africans states.

Alcohol consumption may be: close to risk level, damaging consumption and alcohol addiction. In the United States, it is estimated that there are 4.65% persons that meet the criteria for damaging consumption and 3.81% alcohol addicts (24).

ALCOHOLIC LIVER DISEASE – RISK FACTORS

The occurrence of hepatic lesions in alcohol consumers is influenced by a series of risk factors pertaining to: *alcohol consumption* (quantity drunk, type of alcohol, duration, and frequency), *constitutional factors (*sex, ethnicity), *risk factors for hepatic simultaneous affectation* (viral chronic hepatitis, iron overload syndrome, obesity, genetic factors etc.).

Alcohol consumption

Although there isn't a linear progression type of relationship between ALD incidence and alcohol consumption, numerous data confirm the strong connection between the quantity of alcohol consumed and the debut of alcoholic liver cirrhosis (25, 40).

It is difficult to establish which of the chronic alcohol consumers will develop a severe liver disease. Though it is considered that the occurrence risk for liver cirrhosis is high in consumers with over 10 years of alcohol drinking, 60-80 grams/day in men and 20 grams/day in women, only 6-41% of them develop cirrhosis (8). Some studies show that after large quantities of alcohol consumed (approximately 120 g per day), only 13.5% of consumers are affected by cirrhosis (7). At the same time, an epidemiological study on a large scale proves that every liter of alcohol consumed in excess (irrespective of type) leads to an increase in cirrhosis incidence with 14% in males and 8% in females.

It is relatively difficult to say who will develop or not ALD according to the quantity of alcohol consumed. Nevertheless, risk thresholds as defined by WHO are 21 glasses per week in men (approximately 3 glasses per day, not more than 5 glasses on occasions) and 14 glasses per week in women (about two glasses per day). These thresholds are not risk-free, as there are differences according to nutrition, sex, physical and mental health, and consumption time.

While hepatic steatosis occurs in almost all persons with sustained alcohol consumption, only 10-35% of them develop alcoholic hepatitis, and less, 8-20%, develops liver cirrhosis (6). If the risk for cirrhosis occurrence is no more than 1% in those who consume 30-60 grams of alcohol per day, this risk increases to over 5.7% in persons who drink daily 120 grams of alcohol (23). There is clear and sufficient evidence to confirm that, irrespective of other risk factors associated, the quantity of alcohol consumed is the key element causing ALD.

Beverage type and consumption pattern

All alcoholic drinks are toxic to the liver, but it seems that the risk for ALD is greater in individuals that prefer beer and spirits, and more reduced in wine consumers (18). Also, the risk for liver damage is 2.7 higher in those who usually drink outside meals (9). Daily (or very frequent) alcohol consumption represents a more significant risk for the occurrence of severe forms of ALD than excessive periodical or occasional drinking; the earlier the start, the higher the risk to develop ALD (24).

Sex

The fact that the percentage of females with ALD is smaller than that of men does not mean that women are less likely to develop ALD, but it is a consequence of the fact that men drink alcohol more frequently. Female alcohol consumers are more exposed ALD than men, the main factors which favor the disease being: reduced level of gastric alcohol dehydrogenase, high fat mass, and hormone status (6). While in men the risk for hepatic disease is significant at 14-27 drinks per week, in women, the risk increases at a smaller number of drinks, 7-13 per week (11). Women are twice more sensitive to liver alcohol toxicity and usually develop more aggressive forms of ALD, though they drink less and for a shorter period of time as compared to men (51).

A number of studies showed that at the same quantity of alcohol consumed, blood alcohol content is significantly higher in women than in men (9). It is estimated that women without any other liver condition can consume 14 units of drink per week (one unit equals 8 grams of alcohol) without risk to develop ALD (in the case of men, the "*risk-free*" dose is 21 drinks per week) (23, 30); quantities mentioned are relative, as they do not give any warranty. Other studies lower the risk-free limit to 7 units per week.

Race and ethnicity

Some studies mention that African and Hispanic populations in America register higher rates in mortality and incidence of alcoholic liver cirrhosis as opposed Caucasian population (23). As these differences do not seem to correlate with differences in alcohol quantity consumed, we are inclined to think of the role played by race or some genetic factors in favoring alcohol induced hepatic lesions.

Obesity

Obesity is an independent risk factor for hepatic disease, and non-alcoholic hepatic steatosis incidence, frequently associated to overweight, has been increasing in the past years. The association of the toxic effect of alcohol with non-alcoholic steatosis lesions raises the risk for ALD, with evolution towards cirrhosis; obesity intensifies ALD severity irrespective of the stage: steatosis, alcoholic hepatitis or liver cirrhosis. Taking that into account, for some years now, obesity has become an important health care problem for developed countries, with alarming rising incidence, and it is expected that in the following years we should face a significant increase in ALD cases, in number as well as severity (18).

Nutritional deficiencies

Many alcoholic patients are confronting with different nutritional deficiencies, and in those with alcoholic hepatitis it has been noticed that death risk is strongly correlated with the degree of nutrition (9, 12).

In these cases, mortality increases proportionately with malnutrition severity, reaching 80% in patients with severe nutritional deficiency, as compared to less than 50% in those with normal nutritional status. Malnutrition is a result of poor diet, anorexia, neuropsychological disorders, while

nutritional deficits of vitamin A and E are the most frequently met.

Hepatitis C virus infection

Almost 30% of ALD patients are infected with hepatitis C virus and more than 70% of those with viral chronic hepatitis C have previously consumed significant quantities of alcohol. The relationship between hepatitis C and ALD is proved, the infection with hepatitis C virus being directly involved in the occurrence of severe and advanced forms of ALD (27). The presence of lesions caused by hepatitis C virus is a major risk factor for hepatocellular carcinoma in patients with alcoholic cirrhosis, with a 10-year absolute cumulative incidence of 81% compared to 19% in those without VHC antibodies (28).

Alcohol drinking aggravates hepatic lesions in patients with viral chronic hepatitis C and accelerates the progression towards fibrosis and liver cirrhosis. It has also been noticed that in chronic alcohol consumers, ARN VHC level is significantly higher than in abstinents; last but not least, response to antiviral therapy in alcoholics is much weaker.

In viral hepatitis B, there is no certain data to confirm aggravation of hepatic lesions in patients which associate alcohol drinking (study results are even contradictory), but the effects of alcohol on an already damaged liver are very likely to be more significant than on undamaged liver.

Iron overload syndromes

There is irrefutable proof that hepatic iron overload is a frequent disorder in alcohol consumers; ALD patients have increased hepatic iron load, deposited at hepatocytes level and Kupffer cells. Hepatic iron overload in patients with ALD is considered a predictive factor for mortality (1).

Sinergical hepatotoxic effect of iron and alcohol is proved most convincingly by alcohol drinking association in patients with hereditary hemocromatosis: patients that drink alcohol have a significantly greater risk for severe hepatocytary lesions and cirrhosis occurrence at younger ages in comparison with abstinents (1, 9).

Genetic factors

There are numerous genetic factors that indicate a predisposition to alcoholism as well as to ALD; monozygotic twins are twice likely to become alcoholic and develop cirrhosis than are dizygotic twins (1, 11). It has been noticed that, generally, adopted children from alcoholic parents had a significantly higher alcohol addiction rate (18%) than adopted children with non-alcoholic parents (5%) (6, 11).

Recent studies have shown that variations of *patatin-like phospholipasedomain-containing protein 3* (*PNPLA3*) influence occurrence of alcoholic liver cirrhosis in Caucasian patients.

ALD ethiopathogenesis is not yet fully clear and has several unknown elements; still, one thing is certain: whatever may be the associated risk factors or genetic predisposition, the main triggering element in the genesis of the disease is alcohol consumption.

EVALUATION OF ADJUNCTIVE SYSTEMIC DOXYCYCLINE WITH NON-SURGICAL PERIODONTAL THERAPY WITHIN TYPE 2 DIABETIC PATIENTS

The aim of a study realized by a group of researchers from King Abdulaziz University, King Saud University, Riyadh, Kingdom of Saudi Arabia was to evaluate the effects of systemic doxycycline on clinical and microbiological parameters of diabetic subjects with chronic periodontitis. The 9-month multi-center, randomized, parallel, single-blinded study was conducted from different hospitals in Riyadh, Saudi Arabia between april 2010 - december 2010. A total of 76 diabetic subjects with chronic periodontitis were randomized into 2 groups: control group (CG) received only scaling and root planing (SRP), and the treatment group (TG) receiving systemic doxycycline during the reevaluation visit 45 days after the completion of SRP. Probing pocket depth, clinical attachment level, gingival index, plaque index, and bleeding on probing were collected at baseline, 45 days after SRP, and one, 3, and 6 months after the use of systemic doxycycline. Microbiological analysis comprised the detection of *Tannerella forsythia* (Tf), *Aggregatibacter actinomycetemcomitans* (Aa), *Porphyromonas gingivalis* (Pg), and *Prevotella intermedia* (Pi) by polymerase chain reaction method. Sixty-eight (33 CG and 35 TG) subjects completed the study. Greater reduction in the population of Tf, Pg, and Pi were observed in TG compared with CG in the first month after the administration of systemic doxycycline. The TG showed a significant improvement in gingival index scores compared with the CG by the end of the first and 6 months after the administration of doxycycline. The conclusion of the study was that the adjunct systemic doxycycline can be associated with a reduction of Tf, Pg, and Pi in the first month after the administration of doxycycline with an improvement in the GI. TRACHEOMALACIA IN CHILDREN AND ADULTS - NOT SO RARE AS EXPECTED (Abstract): Tracheomalacia remains a special entity present also in children and adults. Tracheomalacia refers to a weakness of the trachea. Bronchoscopy is the "golden standard" for diagnosis. Differential diagnosis includes foreign body aspiration, difficult controlled asthma and other diseases. This disease may be congenital or it may be acquired. Acquired tracheomalacia can be treated. The main symptoms in tracheomalacia are: dyspnea, sputum production, hemoptysis and cough in adults and expiratory stridor and cough in children. Tracheomalacia could be progressive in some patients. We want to bring to your attention the tools for diagnosis and different methods of treatment. Tracheomalacia is not a rare disease and therefore we need to consider it. **Keywords**: TRACHEOMALACIA, STRIDOR, BRONCHOSCOPY

Tracheomalacia (TM) is still an underdiagnosed disease in both pediatric and adult patients but is not a rare disease. The term malacia is derived from the Greek world "malakia" which means soft.

In TM we can find a reduction and / or an atrophy of the longitudinal elastic fibers of the pars membranacea or impaired cartilage integrity. This cause is the reason of the dynamic narrowing of the transverse or sagittal diameters of the tracheobronchial lumen.

CLASSIFICATION

The most common classification for TM is primary (congenital disease) and secondary (acquired disease). TM is the most common congenital disease of the trachea in premature infants. Acquired TM is more frequently than congenital TM.

The respiratory distress syndrome in premature infants is the most common cause for acquired TM. Other etiology for acquired TM could be: prolonged intubation, tracheostomy, double aortic arch, left atrial hypertrophy, posttraumatic. Compression (vascular, tumors, infections, posttraumatic) could affect the tracheal wall with an increase in the intrathoracic pressure (1, 2).

DIAGNOSIS

Bronchoscopy remains the 'golden standard' for the diagnosis of TM (1). The

pulmonary function test (spirometry) is important because it describes the flow limitation on the expiratory part of flow volume loop with a decreased FEV1, low peak expiratory flow, reduced mid expiratory / mid inspiratory ratio and preservation of the shape of the inspiratory part (2).

It is believed that a reduction by 50-70% of the tracheal lumen is a diagnostic tool for TM. Endoscopic evaluations have resulted in the identification of 3 major models of tracheal lumen narrowing: narrowing of the lateral wall of the trachea ("scabbard type"), antero-posterior narrowing of the trachea ("floppy membrane type') and circumferential narrowing that combines the first two variants (3).

Over the years a lot of diagnosis tools were used: tracheograms, radiographs with comparative inspiratory and expiratory views, CT (computed tomography) scan, MRI (magnetic resonance imaging) scan. CT scan is noninvasive and it reveals anatomic details and the data can be reconstructed into two-dimensional and three-dimensional images (virtual bronchoscopy) (4). Dynamic CT scan images reveal the range intrathoracic tracheal diameters during forced maneuvers. MRI is important for the evaluation of the extrinsic airway abnormalities, for example vascular compression.

Differential diagnoses in children include: foreign body aspiration, difficult asthma and recurrent croup.

PATHOPHYSIOLOGY

Tracheal diameter is influenced during ventilatory movements (exhalation, inhalation), by variations of the intrathoracic pressure. During inspiration the intrathoracic pressure decreases, size of the trachea diameters get larger, and during exhalation, as intrathoracic pressure increase the caliber of the trachea will decrease. These physiological changes enhance in tracheomalacia and become obviously clear in conditions that accompany increased intrathoracic pressure: forced exhalation, coughing, Valsalva maneuver (1, 2).

CLINICAL SIGNS AND SYMPTOMS

The signs and symptoms of TM may appear during the first weeks to the first months of life (5). The most frequently symptoms are expiratory stridor, wheezing and cough. Symptomatology can vary from low-grade intermittent to continuous and severe. Children with TM have an increased relative risk of lower tract illness and a delayed recovery from intercurrent illness. We can find also: cyanosis, respiratory distress, sternal and intercostal retractions, spontaneous hyperextension of the neck, prolonged expiratory phase (6). Some children may have feeding difficulties like regurgitation and dysphagia (7, 8). In severe TM cases can appear increase sputum retention, reflex apnea and stridor during tidal breathing. Sometimes trachea is compressed by the esophagus which produces arterial desaturation, respiratory obstruction and weight loss.

TREATMENT

Intervention is not necessary in some children with TM, because when the child grows the tracheal cartilage strengthens, especially in children with mild and moderate TM, by 18-24 months (9).

Surgical intervention resolves the underlying cause (10).

Asymptomatic patients do not need therapy.

Initially, even in symptomatic patients the treatment is started with conservative

measures (chest physical therapy, control of infection, control of secretions, slow feedings, air humidifier) (11).

When conservative measures failed, surgical therapy is necessary. Tracheostomy, prosthetic stenting, tracheoplasty or tracheal resection with *end-to-end* anastomosis is some options regarding treatment for proximal or diffuse tracheomalacia (8, 9, 10).

Intraoperative bronchoscopy with concomitant aortopexy is the option in case of distal tracheomalacia with tracheo-esophageal fistula or vascular anomalies (12, 13, 14).

In adult patients we can find tracheomalacia in patients who have chronic obstructive pulmonary disease (COPD). It is necessary to treat first the COPD (8, 9, 11).

Stents (metal, silicone) can be placed for tracheomalacia and some authors reported long-term pulmonary function improvement (15, 16, 17). Metal stents are expandable, but could provide secondary reaction: granulation tissue, fracture of the stent (18, 19, 20). Silicone stents could be placed and repositioned by rigid bronchoscopy using general anesthesia but can migrate from inset (21). There are also newer hybrid biodegradable stents, whose efficiency will be evaluated. Some patients may benefit from stenting in the long-term.

CPAP (Continuous Positive Airway Pressure) is very important as treatment for severe TM. Long-term use of CPAP could affect speech and oral feeding (22, 23).

Administration of inhaled bronchodilators in patients with TM is not helpful (24).

CONCLUSIONS

Tracheomalacia is a pathologic condition which causes dynamic narrowing of tracheal lumen. With new tools for diagnosis, TM is identified increasingly often in children and adults too. Early diagnosis of TM and individually management of disease could improve respiratory symptoms and lung function parameters.

ACUTE CARDIOGENIC PULMONARY EDEMA (APE) - ETIOLOGICAL SPECTRUM AND PRECIPITATING FACTORS (Abstract): **Aim:** the analysis of the predisposing and precipitating factors encountered in the anamnesis of the patients hospitalized with acute pulmonary oedema, in order to establish some correlations with the evolution and prognosis. **Material and methods:** The study included 50 patients, 32 males and 18 females, admitted to the Cardiology I Clinic between 2009 and 2013, diagnosed with acute pulmonary oedema upon admission. The following aspects were investigated: cardiovascular antecedents, prodromal elements of the current episode of acute pulmonary oedema (APE), risk factors and associated co morbidities, previous treatments followed at home as well as the triggering factors of the acute episode. **Results:** The main pathology on which the acute pulmonary oedema (APE) episode occurred was represented by: arterial high blood pressure (HBP), dilated cardiomyopathy, ischemic heart disease, valvular heart disease, pre-existing atrial rhythm disorders. The analysis of the factors that precipitated the acute pulmonary oedema episode revealed the following possible triggering conditions: inadequate physical effort on the background of treatment discontinuation, high sodium diet, a prolonged ischemic episode due to inadequate physical effort, rhythm disorder with rapid ventricular response (atrial fibrillation, atrial flutter). In some cases, the risk factors were cumulated. **Conclusions:** Acute pulmonary oedema represents a major emergency that requires immediate admission to hospital and rapid treatment in the emergency department concurrent with the identification of the triggering and precipitating factors. **Keywords:** PULMONARY EDEMA, RISK FACTORS.

Cardiogenic pulmonary oedema represents an important pathology with 10% incidence in patients known with cardiovascular diseases and with a morbidity rate of 50% (1, 2). It is caused by the excessive accumulation of blood plasma at the level of alveoli and pulmonary interstitial space secondary to the increase of the filling pressure in the left heart, which leads to the increase of the hydrostatic pressure in the pulmonary veins and capillaries (1, 2, 3). The main cause is represented by the left heart dysfunction, but there are also some other cardio circulatory conditions that lead to the increase of the pressure in the pulmonary capillaries with the appearance of

the transudate: left heart valvular disorders, cardiac tumours, rhythm disorders with rapid ventricular response (atrial fibrillation, atrial flutter), pulmonary embolism, high blood pressure (2, 3, 4, 5). It represents a major cardiovascular emergency, with life threatening risk, reasons for which the therapeutic intervention has to be fast, prompt, addressing both the involved physiopathological mechanisms and the etiology (5).

Aim of the study: the analysis of the predisposing and precipitating factors encountered in the anamnesis of the patients hospitalized with acute pulmonary oedema, in order to establish some correlations with the evolution and prognosis.

MATERIAL AND METHODS

The study included 50 patients, 32 (64%) males and 18 (36%) females, admitted to the Cardiology I Clinic between 2009 and 2013, diagnosed with acute pulmonary oedema upon admission. All patients were admitted to the emergency unit of the hospital and they were brought by ambulance in most of the cases. Patients were aged between 52 and 85. Being a major emergency, the first therapeutic measures for all patients were initiated in the emergency care unit concomitant with a cardiological examination.

The following steps were undertaken:

- The anamnesis of the patient, with the mention that in the situations in which the condition of the patient did not allow the direct anamnesis, the data was obtained from his relatives or from the previous hospital release documents (patient's previous medical folder respectively).

The following aspects were investigated during the anamnesis:

- Patient's cardiovascular antecedents: high values of blood pressure (HBP), chronic ischemic disease, acute myocardial infarction (IMA), valvular heart diseases, dilated cardiomyopathy (CMD), previously known rhythm and/or conduction disorders, potential surgical interventions at the level of the cardiovascular system;
- Identifying the number of previous episodes of left ventricular insufficiency (cardiac asthma, acute pulmonary oedema) if these occurred;
- Identifying some prodromal elements of the current episode of acute pulmonary oedema (paroxysmal nocturnal dyspnoea);
- The associated risk factors having an impact on the cardiovascular system (smoking, alcohol intake, diabetes);
- Associated comorbidities (thyroid gland disorders such as hypo or hyperthyroidism, chronic obstructive bronchopneumopathy (BPCO), stroke);
- Treatments followed at home up to the moment of coming to the emergency care unit;
- The emphasis was targeted on identifying the precipitating and aggravating factors of the acute pulmonary oedema episode: inadequate physical effort, alcohol intake, paroxysmal rhythm disorder, conduction disorder, prolonged anginous episode, intercurrent respiratory infection, fever, treatment discontinuation, excessive salt intake.

The complete examination of the patients involved: assessing the general state, consciousness, pulmonary auscultation, heart and peripheral arteries (carotid) auscultation, checking of blood pressure (BP).

The paraclinical data were collected concomitantly with the application of the first aid measures in the emergency care unit and therapy:

- Measuring the levels of SaO2, PO2, PCO2, Astrup;

- 12-lead electrocardiogram;
- Continuous EKG monitoring;
- Continuous monitoring of blood pressure (BP) and SaO2;
- Blood sampling for the absolutely necessary usual blood tests: hemoleucogram, renal function, electrolytes, glycaemia, myocardial cytolysis enzymes (aspartate aminotransferase (AST), creatine kinase (CK), creatine kinase MB (CKMB), lactate dehydrogenase (LDH)), coagulation tests;
- Echocardiography in the Emergency Room: 2D, M mode and Doppler in order to assess left ventricular systolic and diastolic function and to confirm the etiology of heart failure.

RESULTS AND DISCUSSION

In our study 50 patients, 32 males and 18 females, aged between 52 and 85, diagnosed with acute pulmonary oedema were admitted to the Cardiology I Clinic, between 2009 and 2013 (fig.1).

Age distribution of the patients from the group was as follows (fig.2).

Fig. 1. Gender distribution of patients

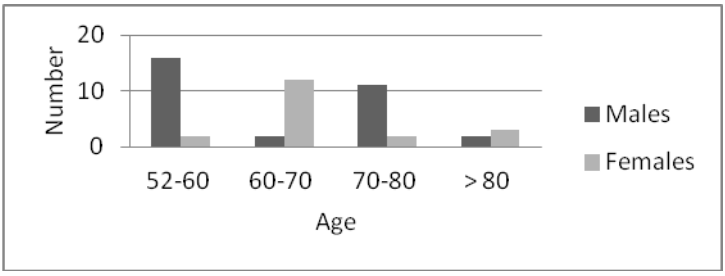

Fig. 2. Age distribution for the patients with pulmonary oedema

The anamnesis of the patients in the group revealed the following data:

- high blood pressure present in 20 patients, 11 males and 9 females;
- dilated cardiomyopathy present in 15 patients, 13 males and 2 females;
- 3 patients presented significant hemodynamic valvular heart disorders: one male presented aortic stenosis and 2 females presented mitral stenosis and aortic stenosis respectively;
- the ischemic cardiac disease was present in 12 patients from the group with high blood pressure, 8 males and 4 females respectively, of which: 2 males had acute myocardial infarction (AMI) before, 6 males presented different forms of angina pectoris; one female had acute myocardial infarction (AMI) before and 3 females, different forms of angina pector-

is;

- rhythm disorders in 16 patients as follows: 12 with atrial fibrillation (7 males and 5 females), 4 with atrial extrasystolic arrhythmia and ventricular extrasystolic arrhythmia (2 males and 2 females).

Of the total number of patients, 33 (66%) were at their first acute pulmonary oedema episode, and 17 (34%) at their second (fig. 3).

The analysis of the associated risk factors in the patients from the group revealed the following: of the total number of patients, 21 were smokers, 23 reported chronic alcohol consumption, dyslipidemia was present in 18 patients, 6 of them being under treatment with statin. Diabetes was present in 6 males and 3 females, 5 of them being under treatment with insulin; 3 patients had associated thyroid pathology; 4 of them had antecedents of stroke; 5 had chronic obstructive bronchopneumopathy (BPCO) and presented chronic renal disease (fig.4).

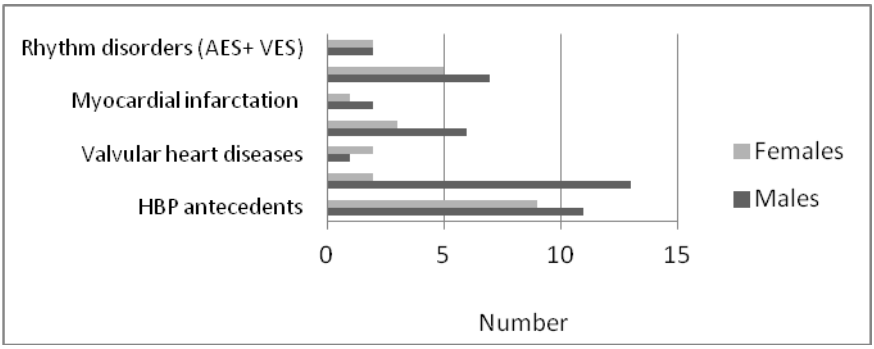

Fig. 3. Pathological antecedents present in patients in the study

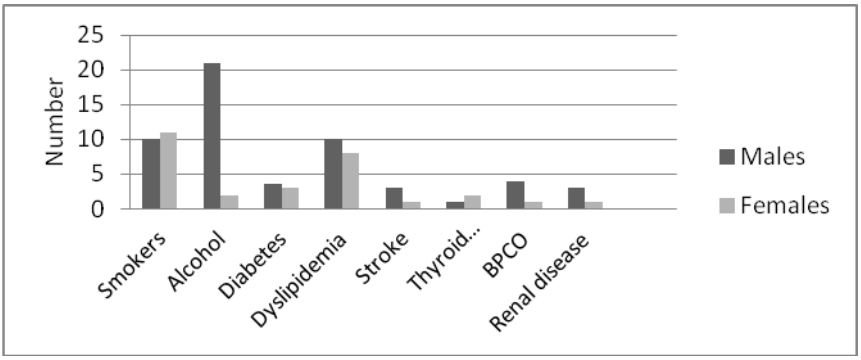

Fig. 4. Risk factors present in the patients diagnosed with acute pulmonary oedema.

Treatments followed by the patients in the group before the acute pulmonary oedema (APE) episode were different. Patients with high blood pressure were under different therapeutic schemes with calcium blocker, beta blocker, conversion enzyme inhibitor (ACE) and diuretic. The oral anticoagulant was used in 22 patients, 14 of them receiving platelet antiaggregants.

Three patients from the group of those with thyroidian pathology were under treatment with antithyroid drugs or Euthyrox.

Patients known with chronic obstructive bronchopneumopathy had Miofilin in their scheme of treatment (used as a bronchodilator) and sympathomimetic medication in some cases associated with corticotherapy in minimal doses (fig.5).

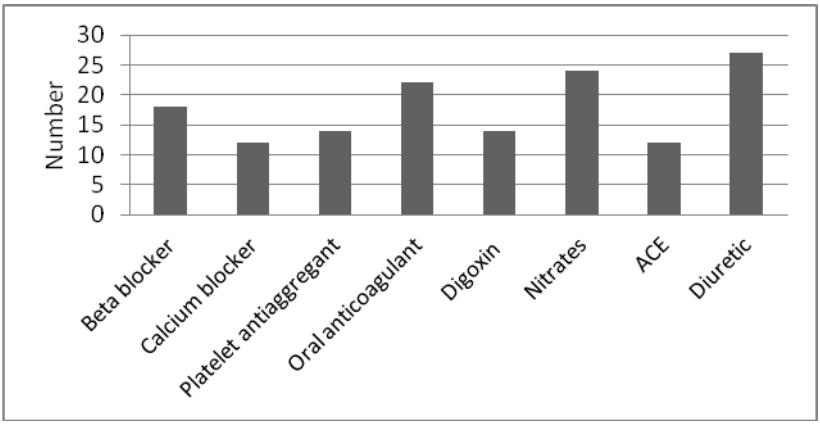

Fig. 5. The medication administered before the APE episode.

The analysis of the factors that precipitated the acute pulmonary oedema (APE) episode revealed the following possible triggering conditions:

- Inadequate physical effort in the context of treatment discontinuation in 27 patients (20 males and 7 females);

- High sodium diet associated with inadequate physical effort and treatment discontinuation in 12 patients (8 males and 4 females);

- Prolonged ischemic episode in the context of inadequate physical effort in 5 patients (3 males and 2 females). All these patients were known with ischemic cardiac disease;

- Rhythm disorder with rapid ventricular response (atrial fibrillation, atrial flutter) in 15 patients (13 males and 2 females);

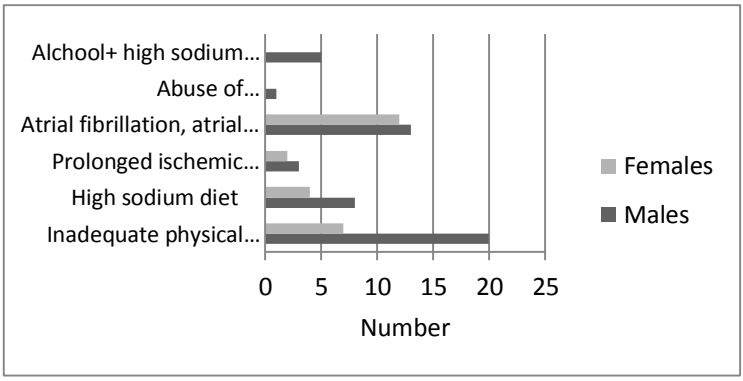

Fig. 6. Factors that precipitated the onset of acute pulmonary edema

- Sympathomimetic drugs abuse reported by one patient;

- For 5 patients (all male) the precipitating factors were cumulated: inadequate physical effort associated with high sodium diet, together with alcohol intake, on the background of treatment discontinuation (fig. 6).

CONCLUSIONS

The acute pulmonary oedema episode was solved faster in the case of the patients for whom the triggering factor was the high blood pressure (HBP) and of those who were at their first episode.

In patients having dilated cardiomyopathy and mitral or aortic valve disorders as an etiologic substrate, the evolution was more severe, requiring special therapeutic measures. The severity was amplified by the coexistence of the low cardiac output syndrome in the respective cases.

Patients who were at the second episode of acute pulmonary oedema had a more severe evolution.

Treatment discontinuation at home in the case of some patients associated with chronic alcoholism was a clear aggravating factor for the evolution.

PRURITUS IN THE ELDERLY. PATHOPHYSIOLOGICAL, CLINICAL, LABORATORY AND THERAPEUTIC APPROACH

PRURITUS IN THE ELDERLY. PATHOPHYSIOLOGICAL, CLINICAL, PARA-CLINICAL AND THERAPEUTIC APPROACH (Abstract): Generalized pruritus is a common symptom in elderly patients, with severe impact on the quality of life. The diagnosis of senile idiopathic pruritus is made after the exclusion of a systemic disease such as chronic renal disease, hepatobilliary disease with cholestasis, thyroid dysfunctions, drug-induced hypersensitivity reactions, visceral or hematological neoplasia, and primitive dermatological distinct conditions. The pathophysiological mechanisms are still unclear. A critical role is considered to be played by changes related to skin aging, cutaneous nerve supply and other nervous system components. The clinical approach requires a thorough assessment of general health status. In primary skin conditions, a biopsy and direct immunofluorescence (DIF) are required, while in pruritus associated with a systemic disorder, the assessment of hematological, biochemical and immunological parameters and imaging are necessary. The treatment of a patient with chronic pruritus is often palliative and individualized, with emollients, sedating and non-sedating antihistamines, tricyclic antidepressants, gabapentinum, and narrow-band UVB phototherapy. Pruritus associated with systemic disease may be alleviated by etiologic treatment. **Keywords**: PRURITUS, PATHOPHYSIOLOGY, ELDERLY, SYSTEMIC DISEASE, TREATMENT

Generalized pruritus is a common symptom in elderly patients, with severe impact on their quality of life. It is an annoying symptom, considered an “alarm system” or a self-defense mechanism, the same as other cutaneous sensations such as pain, tactile sensation, vibrations, cold or hot.

Pruritus is a symptom occurring in about 20% of the adult population.

An underlying systemic disease is reported in 10 - 50% of the patients who see a doctor for pruritus. Thus, it occurs in 22 - 66% of the hemodialysis patients, 30% of the patients with chronic renal failure not undergoing dialysis, 60% of the patients with primary biliary cirrhosis, 48-70% of the patients with polycythemia vera, 4 - 11% of the patients with untreated Graves disease, 35% of the patients with Hodgkin’s disease, 10% of the patients with non – Hodgkin lymphoma.

The malignancy rate in patients with generalized pruritus is thought to range between 1 and 8%. Pruritus occurs in very few cases of diabetes, hypothyroidism and leukemia (1, 2).

PATHOPHYSIOLOGY

Various mechanisms involve a complex network of cutaneous cells (keratinocytes, mast cells, inflammatory infiltrate cells: lymphocytes, eosinophils), which interact with unmyelinated slow-conducting polymodal C fibers and A-delta nociceptive neurons, with free terminations, located in the vicinity of the dermoepidermal junction or in the epidermis (2, 3, 4, 5).

The following mediators were found to play an important role: histamine, serotonin, bradykinin, protease (for instance mast cell tryptase), endothelin, NGF, brain-derived neurotrophic factor, neurokinins, neuropeptides (substance P), gastrin-releasing peptide, cytokines such as IL31, autotaxin, histamine H_4 receptors (6).

Senile pruritus or Willan's itch is induced by age-related tegument changes and cutaneous nervous fibers distribution alteration. Also, any increase in the expression of the vanilloid transient receptor 1 (TRPV1), which is a member of the non-selective cation channel family whose activation determines an influx of bivalent and monovalent cations (for instance, Ca2+, Na+, Mg2+) in aged human skin, would be suggestive of the involvement of this receptor in different senile cutaneous symptoms such as pruritus and neurogenic inflammation (2, 6, 7).

In renal pruritus (chronic renal failure, especially in hemodialysis patients), pruritus is rather due to the high level of bivalent ions (calcium, magnesium, phosphate), also detected in patients with cutaneous pruritus of different etiology, than to the high level of circulating histamine associated with a large number of mast cells in various organs. Other factors that may be involved in renal pruritus are: lower transepidermal release rates of pruritogenic substances, xeroderma, higher bile acid levels in the serum, higher vitamin A levels in the epidermis, serum serotonin increase. Also, in chronic renal failure, pruritus may be a possible symptom of peripheral neuropathy. Enolaso-positive non-specific nerves were found to proliferate in the epidermis of uremia patients. Also, opioid substance accumulation and μ-opioid receptor over-expression and activation could account for renal pruritus. Another hypothesis supports the role of systemic inflammatory reactions in these patients, which trigger the over-expression of activated Th1 lymphocytes, which secrete the IL2 responsible for pruritus; hence, the efficiency of the UVB phototherapy, and thalidomide and tacrolimus treatment, which target inflammation mediators. Pruritus severity in uremia patients is correlated with high ferritin and low transferrin and serum albumin levels (2, 6).

In cholestatic pruritus, the accumulation of specific pruritogenic intermediaries in bile salt synthesis is thought to determine hepatic lesions and pruritogenic substance release. Rifampin and ursodeoxycholic acid diminish the intrahepatic concentration of bile salts and ameliorate hepatic pruritus. This would also involve the accumulation of endogenous opioids, which play a certain role in pruritus modulation and cerebral opioidergic tonus increase; therefore, cholestatic pruritus is partially ameliorated by opioid antagonist delivery (2, 6).

In hematologic pruritus, iron deficit may lead to pruritus occurrence through a variety of metabolic pathways. In *polycythemia vera*, pruritus is influenced by the large number of circulating basophils and skin mast cells, and it is typically enhanced when the contact with hot water ceases. In addition to iron, other major hematologic

pruritus mediators are mast cell prostaglandins and platelet degranulation products, which induce serotonin and prostanoid release (2, 6).

In endocrine thyropathy pruritus, the thyroid hormone hypersecretion specific to hyperthyroidism may activate the kinins resulting from high tissue metabolism or it may reduce pruritus threshold as a result of heating and vasodilation. In hypothyroidism, pruritus follows xerosis. In diabetic patients, pruritus is correlated with metabolic anomalies, anhidrosis, diabetic neuropathy and autonomic dysfunction (2, 6).

Pruritus associated with malignant processes may be accounted for by the release of tumor toxins. Pruritus mediators in Hodgkin's disease are leukopeptidase and bradykinin released as a self-immune response directed against malignant lymphoproliferative cells. In carcinoid syndrome, pruritus is triggered by serotonin (2, 6).

CLINICAL APPROACH

The detailed history and thorough general physical and tegument examination play a critical role in determining the cause of pruritus.

The detailed history should include the onset, duration, severity, location and temporal relation with triggering factors such as drugs, bath, emotional stress, and data on possible alcohol abuse, which may indicate a chronic hepatic disease. The history should also provide information on patient's mental health in order to exclude a possible psychiatric cause of their pruritus.

The clinical examination may reveal xeroderma as a possible cause or just as a coincidental symptom, as well as signs that allow differentiating systemic causes from primary dermatological conditions. Thus, the skin may look normal or it may exhibit secondary lesions: excoriation, prurigo nodularis, lichen simplex chronicus, signs of secondary suprainfection, "butterfly sign" (hypo-pigmented or normal skin area on the postero-median thorax and post-inflammatory pigmentation areas which are easy to reach by patient's hands).

Renal pruritus may be accompanied by: diffuse xerosis, "half and half nails" associated with signs of peripheral neuropathy and uremia.

Signs of hepatic condition present in cholestatic pruritus are: jaundice, spider angiomas, white nails, xanthelasma, Dupuytren's contracture, gynecomastia in males, ascites, splenomegaly.

Hematological pruritus determines: paleness (anemia, hyposideremia), glossitis and angular cheilitis, "red face" (perioral, cheek, nose and ear erythema), whereas in polycythemia vera it also associates hypertension and splenomegaly.

Well-defined hyperpigmentation, ichthyosis, painless lymphadenopathy and splenomegaly are characteristic of paraneoplasic pruritus in Hodgkin's disease.

Diagnostic keys: generalized pruritus due to a systemic disease has an insidious onset; generalized pruritus in an old man with iron deficit but without anemia raises the suspicion of a neoplasm.

The causes of pruritus occurrence in systemic diseases are partially elucidated. Bile salts, histamine, opioids and unidentified pruritogenic substances in injured hepatocytes are thought to be involved in cholestatic pruritus. Pruritus may be correlated with primary biliary cirrhosis cholestasis, sclerosing cholangitis, chronic virus C hepatitis, choledocholithiasis, obstructive pancreas or bile duct carcinomas, pregnancy, and terminal hepatic illnesses regardless of etiology. Also, pruritus may be

associated with drug-induced cholestasis: chlor-propamide, salbutamol, phenothiazine, anabolic steroids, oral birth control pills, and erythromycin.

Hematologic prurits may either be induced by iron deficit, or occur in polycythemia rubra vera, hypereosinophilic syndrome, primary thrombocythemia, myelodysplastic syndromes.

Endocrine pruritus accompanies hypo-/hyperthyroidism, diabetes mellitus, hyperparathyroidism, hypoparathyroidism.

Pruritus associated with neoplastic conditions occurs in Hodgkin's disease, non-Hodgkin lymphomas, leukemia, paraproteinemia, carcinoid syndrome, SIPPLE syndrome (multiple endocrine neoplasia), solid tumors (gastro-intestinal tumors, SNC, pulmonary tumors).

Other conditions that materialize in pruritus are drug-induced rash-free pruritus (prurit sine materia), mastocytosis, HIV infection, AIDS.

LABORATORY APPROACH

Whenever primary cutaneous lesions are present (dermatitis herpetiformis, bullous pemphigoid, mastocytosis), cutaneous biopsy and possibly direct immunofluorescence and special stains are required.

Suspicion of a systemic cause requires: hematologic, biochemical and immunological tests (complete blood count, leukocyte differential count, ESR, electrolyte dosage, total protein test and protein electrophoresis, functional renal tests, glycemia, hepatic enzymes, uric acid, serum iron, alkaline phosphatase, bilirubin (high in cholestasis), hepatitis B and C serology, thyrotropin and thyrosine indicative of thyroid dysfunctions, IgE, PSA, urine exam for hydroxyl-indol-acetic acid (5-HIAA) and mast cell metabolites, folic acid dosage, zinc, vitamin B_{12}, porphyrin, antimitochondrial antibodies (positive and with 98% specificity in primary biliary cirrhosis), parathormone level, coproparasitologic exam, hidden hemorrhage); diagnosis confirmation procedures: retrograde cholangio-pancreatography, colonoscopy; necessary imaging investigations: chest X-ray, abdominal ultrasonography, tumor detecting CT/ IMR, ganglion ultrasonography.

THERAPEUTIC APPROACH OF PRURITUS

Possible treatment stages include: when the cause in not identified: avoid triggering factors, emollients, symptomatic therapy (non-sedating H_1 antihistamines), topical corticotherapy; when the cause has been detected: etiologic treatment; when the cause is unclear and the patient has not responded to previous therapies, and when secondary lesions are present: administer capsaicin, calcineurin inhibitors, cannabinoid agonists, naltrexone, gabapentinum, UV therapy, immunosuppressants (cyclosporine), tricyclic antidepressants (doxepin) and tetracyclic antidepressants (mirtazapine).

Elderly patients in whom pruritus is suspected to have a systemic cause are given: gastroenterological exams (to detect hepatobiliary conditions), hematologic/ oncologic exams (to detect malignant hematologic conditions, organic neoplasm), nephrological exams (to detect chronic renal conditions), endocrine exams (to detect thyroid conditions), surgical procedures (for renal/ hepatic transplant or obstruction removing stent in primary sclerosing cholangitis).

ETIOLOGIC TREATMENT

Therapeutic options available in renal pruritus are represented by physical, topical

and systemic treatment. Physical treatment - UVB phototherapy - reduces cutaneous phosphorus, decreases the number of dermal mast cells, and reduces vitamin A level in the epidermis. Topical treatment is used in localized pruritus and includes 0.025% capsaicin cream, 0.03% tacrolimus ointment (calcineurin inhibitor able to decrease Th1 lymphocytes differentiation and reduce IL2 production), 3-6% gabapentinum cream (ameliorates localized neurogenic pruritus), gamma-linolenic acid. Systemic treatment: the most common therapy of renal pruritus in dialysis patients is narrow-band UVB phototherapy associated with activated carbon administered orally. Another option in patients not responding to conventional therapy is thalidomide which decreases Th lymphocytes and inhibits TNF alpha production, or nicergoline and free fatty acids as the ones found in common evening primrose, gabapentinum or opioid antagonists, butorphanol and nalfurafine (2, 8, 9).

Cholestyramine is the first line therapy in cholestatic pruritus. It is followed by rifampine (rifadin, an antibiotic inhibiting RNA synthesis in bacteria and also hepatic biliary acid re-uptake, by detoxifying them), opioid antagonists (i.v. naloxone or oral naltrexone or oral butorphanol), ursodeoxycholic acid and s-adenosyl-methionine (efficient in pregnancy cholestasis and generally in patients with intrahepatic cholestasis) (2, 8).

Iron therapy in hematologic pruritus normalizes ferritin levels. The first therapeutic option in polycythemia vera is aspirin, which decreases platelet degranulation and serotonin and prostaglandin release. Other therapeutic options are cimetidine, danazol, UVB phototherapy, cholestyramine. In Hodgkin's disease, pruritus may be ameliorated by thalidomide (2, 8).

Pruritus due to hypothyroidism is ameliorated by topical therapy with emollients, whereas systemic pruritus responds well to substitution thyroid hormones.

Pruritus associated with chronic dermatosis responds to basic disorder therapy or to non-specific treatments such as topical cannabinoid agonists.

Uncontrollable pruritus may be reduced by UVB phototherapy, cholestyramine, naloxone and activated carbon.

Limited data suggest that gabapentinum, focal/zonal cutaneous stimulation, serotonin antagonists and UVB phototherapy may ameliorate senile idiopathic pruritus (6, 7).

PATIENT EDUCATION AND PROGNOSIS

Common cutaneous xerosis in the elderly enhances pruritus. Consequently, recommendations include emollients, avoidance of excessive bathing, dry environments, alkaline soaps and irritating fabrics.

Prognosis depends on complications, which are: debilitating insomnia, suicidal ideation, prurigo nodularis, and lichen simplex chronicus.

Poor prognosis is correlated with symptom severity. Thus, generalized pruritus is an example of long-term mortality marker of approximately 3 years in hemodialysis patients and it has poor significance in Hodgkin's disease patients. The recurrent nature of pruritus after visceral neoplasm therapy is a marker of cancer recurrence.

CONCLUSIONS

Pruritus is a common symptom in the elderly, yet age, just as sex, does not correlate with pruritus occurrence in patients with systemic conditions.

Idiopathic senile pruritus is an exclusion diagnosis, which requires investigation of a basic systemic disease (thyroid, hematologic, cholestatic or chronic renal condition, or more rarely as paraneoplastic phenomenon or cerebral infarction aftermath). Initially negative paraclinical tests do not exclude a systemic disease and the screening must be repeated every 3-6 months if the clinical suspicion remains.

Pruritus in old age is a difficult symptom to treat. The elucidation of the pathological mechanisms involved may have therapeutic advantages both in idiopathic senile pruritus and in pruritus triggered by systemic diseases.

A symptomatic patient-specific therapy is preferred in the absence of an etiological diagnosis, especially considering that the mere use of emollients may be impossible because the physical disabilities proper to seniors and the adverse effects of therapy are more common in seniors, since the associated diseases may alter drug metabolite pharmacokinetics and polypragmasia increases the risk of adverse reactions correlated with drug interactions, and failing cognitive functions induce low therapy compliance in the elderly.

The therapeutic options in severe therapy-resistant pruritus of systemic origin are: IL31 antagonists, neurokinin 1 receptor anagonists or anti H4 which are still under clinical study.

THE QUALITY OF MEDICAL CARE DURING AN ACUTE EXACERBATIONS OF COPD (Abstract): Chronic obstructive pulmonary disease (COPD) is a significant cause of global morbidity and mortality, with a substantial economic impact. Acute exacerbations of COPD (AECOPD) represent a dramatic event in the course of the disease; is an important cause of morbidity and the fourth cause of mortality worldwide. During the hospitalization for AECOPD mortality is 10%. AECOPD are also associated with a significant reduction of functional capacity and health-related quality of life. Despite these alarming evidence-based data the response of the healthcare system globally is not adequate to the gravity of the situation. A recently published study done in a Canadian hospital reveals that the treatment of the AECOPD is sub-optimal. The management of the COPD exacerbations prior, during and after the hospitalization showed inadequate adherence of the physicians (respirologists, internists and hospitalists) to the current guidelines. This review outlines the worrisome findings of this study and the proposed measures suggested by the authors in order to optimize the management of AECOPD. **Keywords:** COPD, ACUTE EXACERBATION OF COPD, LUNG ATTAK, TRIPLE THERAPY FOR COPD, HOSPITALIZATION, ADHERENCE TO GUIDELINES

Sandhu et al. published in the May 2013's issue of the Canadian Respiratory Journal a study ("Variations in the management of acute exacerbations of chronic obstructive pulmonary disease") that highlights worrisome observations regarding the management of acute exacerbations of Chronic Obstructive Pulmonary Disease (COPD). The lack of optimal care for these patients is disappointing in the light of documented poor prognosis associated with acute exacerbations of COPD (AECOPD). Our intention is to discuss the findings of this study and its proposed solutions.

COPD is defined by Global Initiative for Chronic Obstructive Lung Disease (GOLD) as "a common, preventable and treatable disease characterized by persistent airflow limitation that is usually progressive and associated with an enhanced chronic inflammatory response in the airways and in the lung to noxious particles or gases. Exacerbations and co morbidities contribute to the overall severity in individual patients" (1). Burden of Obstructive Lung Disease (BOLD) study estimate the prevalence of moderate and severe COPD, confirmed by spirometry, at 10% respectively 11.8% in

men and 8.5% in women (2).

COPD exacerbation represents an acute event characterized by the worsening of the respiratory symptoms beyond daily variations and which necessitate the change in the medication. The acute exacerbations and comorbidities contribute to the severity of COPD which is an important cause of morbidity and mortality globally (1).

COPD exacerbation, known also as a "lung attack" represents the fourth cause of mortality in the world and is a dramatic event; mortality in the hospital with an acute exacerbation is 10% and the mortality at 1 year following a hospitalization for an acute exacerbation is 25% (one in four patients will die in the following year after a hospitalized acute exacerbation) (3).

The average COPD patient with moderate or severe disease experiences 2-3 acute exacerbation/year (4). There is a documented decline in the lung function following an acute exacerbation (5, 6). Acute exacerbations of COPD are associated with significant reduction in functional exercise capacity and health-related quality of life measurements even in patients that underwent pulmonary rehabilitation prior to the "lung attack" (7). Early and adequate therapy improves the quality of life of these patients and can lower the hospitalization risk (8). This evidence – based data is worrisome but the response of healthcare systems around the world is disappointing (9).

A group from Vancouver (Sandhu et al.) did a retrospective study of the charts of 293 patients, admitted in a tertiary hospital for COPD exacerbation in 2009 (10). They examined the management of the COPD exacerbations prior, during and after the hospitalization to assess the adherence of the physicians to the current guidelines.

Inclusion criteria refer to self-reported previous diagnosis of COPD and primary discharge diagnosis of AECOPD (additional hospital visits under 28 days from the primary discharge were considered relapses).

Exclusion criteria were: the patient didn't have a pre-existing diagnosis of COPD; severe pre-existing mental issue and the AECOPD was the secondary diagnostic criteria.

The demographic characteristics of these patients are: mean age: 74.2+/- 11.4; sex: 52.9 % male and 47.1% female; previous family doctor: 95.5%; current smokers: 34.9% and co morbidities: 0 – 25.6%; 1 – 33.1%; 2 – 28.0%; 3 – 13.3% or co morbidities: 21% - heart failure; 9.5% - lung cancer; 23.6% - diabetes mellitus; 10% - depression.

Patient analysis shows that no information on lung function was collected (FEV1). The patients were admitted to respirologists, internists and hospitalists. Arterial blood gases (ABG) were performed in patients admitted to the respirology service: 68.4% compared with 48.4% for internists and 21.0% for hospitalists. Chest-X-rays were universally done (96-98%).

Patients'COPD maintenance medications on arrival were: 58% salbutamol, 40% ipratropium, 47.1% on a combination of ICS (inhaled corticosteroids) and LABA (long acting bronchodilator agonist), 17.7% tiotropium, 13.7% prednisone and 18.6% antibiotics. In total 82.6% of the patients were treated with > 1 maintenance medication.

This Canadian study reveals some worrisome findings. Current guidelines (1, 11, 12) highlight the "triple therapy" for the maintenance of moderate and severe COPD: ICS + LABA +/- LAMA (long acting anticholinergic muscarinic agonists). Before admission to the hospital less than half of the COPD patients were treated

with a combination of LABA + ICS or with LAMA. Only 82.6% of the patients were treated before the admission in the hospital with one or more COPD medication and only 17.7% of them were treated with an inhaled long acting anticholinergic (ipratropium). A small percentage of these patients were seen by a respirologist as outpatients (15.4%). Only 18.6% of the patients received antibiotics prior to their admission and only 13.7% received systemic cortisol.

The current guidelines for AECOPD (1, 14) recommend the prescription of a short acting bronchodilator with or without a short acting anticholinergic. Oxygen should be given to maintain the saturation between 88-92% and systemic corticosteroid (30-40 mg Prednisolon/day, 10-14 days) are recommended.

Antibiotics are recommended only in the presence of three cardinal symptoms: worsening of dyspnea + increased sputum production + purulent sputum or antibiotics for the patients that necessitate mechanical ventilation. During the hospitalization only half of the COPD patients of this study received the "acute triple therapy" (inhaled bronchodilator + systemic corticoids + antibiotics). 16% of the admitted patients did not receive antibiotics.

GOLD guidelines recommend to test the arterial gases only if the patient is hypoxemic (SO_2 < 92%). The spirometry is not recommended during an AECOPD. During the hospitalization of the COPD patients of this study very few arterial blood tests were performed.

The patients were admitted at: 44.9% internal medicine, 27.5% at respirology and 5.1% in Intensive Care Unit (ICU). Suboptimal treatment was offered by all three categories of physicians but the data shows that the internist and the hospitalists managed less optimal than the respirologists. An explanation might be the fact that the patients admitted under the internal medicine and hospitalists were older than those admitted under the respirologists (14). The elderly have more comorbidities compared with the younger patients admitted by respirologists and the prescription of systemic corticosteroids may have been limited by possible drug side effects. The data shows that the patients admitted under respirology were sicker: respiratory rate was higher (tachypnea), SO_2 lower, $PaCO_2$ higher (CO_2 retention), more acidotics.

The respirologists performed more arterial blood gases (64.4% versus 48.4% internists and 21% hospitalists). 78.9% of the patients admitted under the respirologists received corticosteroids compared with only 53.2 % of the patients admitted under the internists.

Despite the fact that the management of the patients with acute exacerbation admitted under the internists and hospitalists was less optimal compared with the management offered by respirologists, it is interesting to noticed that the deficiency was not translated into a significant increased of relapses or by an increase of mortality. 52.6% of the total number of the patients had a new exacerbation at up to 28 days after discharge.

Clinical studies showed that the maintenance "triple therapy" (LABA + ICS + LAMA) reduces the number of the acute exacerbations with risk of hospitalization (severe exacerbations) but does not reduce the general risk of exacerbation, for the patients with an FEV1 < 65% (15). At discharge, only 25.5% of the COPD patients received a prescription for the maintenance "triple therapy" (LABA + ICS + LAMA).

There is no mention of recommending Pulmonary Rehabilitation even with the recent evidences that the use of pulmonary rehabilitation immediately after an acute exacerbation of COPD is beneficial (16).

CONCLUSIONS

The management of the AECOPD is deficient especially when the patients are treated by the non-respirologists. This study enrolled only 293 patients thus it might be possible that it does not have enough statistical power. A suggestion made by the authors of this study is the introduction of the pre-printed prescriptions (orders); a list format. These prescriptions should be available for the physicians who admit these patients to the hospital (emergency room).

The prescription should contain: a bronchodilator, an inhaled corticosteroid and an antibiotic if the patient has purulent sputum or requires mechanical ventilation. The admitting physician is asked to check the appropriate items on the form and to sign the prescription thus the nurse can start the administration of the treatment right away.

Consequently, will not be necessary that the internist or the hospitalist to know the current recommendation for the treatment of stable or acute COPD nor to know when to prescribe the maintenance "triple therapy" at the discharge.

This Canadian study highlights the importance of continue medical education and it is not surprising that the respirologists managed better the acute exacerbations of COPD compared with the internists and hospitalists.

The respirologists adhere more to the current guidelines and this study invites them to reflect about the modalities to improve the management of these very sick patients. It is the respirologists duty to do a better job regarding the implementation of the current guidelines in regards with the acute and maintenance therapy for COPD in internal medicine and family practice, because when you can't breathe, nothing else matters !

ADHESION AND BIOFILM FORMATION BY PERIODONTOPATHOGENIC BACTERIA ON DIFFERENT BRACKETS

The aim of the study realized by a group of italian researchers from the Department of Public Health and Infectious Diseases- Sapienza University of Rome was to compare early bacterial adhesion and biofilm formation of common and uncommon periodontal pathogens on a variety of commercial brackets in vitro. In vitro adhesion and biofilm formation of 4 bacterial strains on 15 different commercial brackets, in standard culture mediums with and without addition of either serum or human saliva was evaluated by quantitative real time PCR after extraction of bacterial DNA. The results showed that the materials significantly influenced bacterial adhesiveness in a species-specific way. Titanium and gold brackets constantly yielded the lowest values with all tested bacteria and in all tested conditions. Bracket materials and medium of growth significantly influenced biofilm formation. The conclusions of the authors were that the materials and environmental conditions significantly influence biofilm formation by periodontal pathogens at the surface of brackets. Whenever possible brackets should be kept far from the gingival margin and if this is not possible, brackets made of gold, titanium, and ceramic should be preferentially used. (Passariello C, Gigola P. Adhesion and biofilm formation by periodontopathogenic bacteria on different commercial brackets. *Eur J Paediatr Dent*. 2013;14 (3) :199-203).

HEART RATE PARTICULARITIES IN CHRONIC OBSTRUCTIVE PULMONARY DISEASE

M. Roca[1], F. Mitu[2], Iulia-Cristina Roca[3], T. Mihăescu[4]

HEART RATE PARTICULARITIES IN CHRONIC OBSTRUCTIVE PULMONARY DISEASE (Abstract): Autonomic nervous system dysfunction proved in chronic obstructive pulmonary disease (COPD) patients might determine an elevated cardiovascular risk by heart rate alteration. **Aim:** To assess the particularities of heart rate as a possible cardiovascular risk factor in COPD patients. **Materials and Methods:** This prospective, case-control study comparatively analyzed the pulse rate continuously recorded with a polygraph in 32 COPD patients and 29 healthy subjects during rest (supine and sitting position) and during submaximal exercise (6-minute walk test). The relation between pulse rate and respiratory, functional or clinical alterations was analyzed in COPD patients. **Results:** The mean pulse rate was significantly higher during rest and exercise in COPD patients compared with the controls. However, the chronotropic response determined by exercise was similar in COPD and control groups: 55.19 beats/minute and 57.21 beats/minute, respectively ($p=0.686$). The mean pulse rate during exercise correlated with hypoxemia ($r=-0.354$, $p=0.47$) and with resting pulse rate ($r=0.871$, $p<0.001$ for supine position). **Conclusions:** COPD associates elevated pulse rates during both rest and exercise. Hypoxemia and resting pulse rate are determinatives of chronotropic response during submaximal exercise in COPD patients. **Keywords**: COPD, RESTING PULSE RATE, CHRONOTROPIC RESPONSE

One of the specific characteristics in COPD patients is represented by the presence of complex chronic comorbidities (1). Cardiovascular diseases represent important comorbidities, resulting in 26% of cause-specific mortality in COPD patients: 16% sudden death, 4% stroke, 3% myocardial infarction, 3% congestive heart failure (2). COPD associates an increased risk of developing acute cardiovascular events such as cardiac arrhythmia, deep vein thrombosis, pulmonary embolism, myocardial infarction, and stroke (3). However, the complex pathogenic relation between COPD and cardiovascular diseases is poorly understood, although there is evidence for the involvement of some common risk factors, such as smoking.

Patients with COPD have a lower heart rate recovery after exercise than healthy people. This alteration was proved as a strong predictor of mortality in COPD patients (4). Some researchers suggest that autonomic nervous system dysfunction

demonstrated in COPD patients may alter the cardiac autonomic modulation and subsequently the heart rate (5). These alterations might partially explain the increased cardiovascular risk in COPD patients. Given the pathogenic and prognostic implications of heart rate, our study aimed to assess the particularities of heart rate as a possible cardiovascular risk factor in COPD patients.

MATERIAL AND METHODS

To achieve our goal we performed a prospective, case-control study in which we compared heart rate in COPD patients and subjects without lung diseases.

The study included patients admitted to the Iasi Clinic of Pulmonary Diseases in the interval April 2011 - September 2012 diagnosed with COPD according to the criteria in Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines: chronic dyspnea, cough, or sputum production, and persistent airflow limitation, confirmed by spirometry (a ratio of forced expiratory volume in 1 second (FEV1) to forced vital capacity (FVC) of <0.7 after bronchodilator administration (6). The control group included subjects without history of lung diseases and without clinical symptoms compatible with COPD diagnosis or respiratory dysfunction, according to the results of pulmonary function tests. COPD patients and controls were matched for sex and age. Male gender and age between 45 and 85 years were inclusion criteria for both COPD and control group. History of heart rhythm disorders represented an exclusion criterion for both COPD and control group.

The study protocol included clinical and anthropometric assessment of the subjects: body height and weight were measured and body mass index (BMI) was calculated. The degree of dyspnea was estimated for COPD group using the Modified Medical Respiratory Council (MMRC) dyspnea scale (7). Health impairment in COPD patients was measured by St George's Respiratory Questionnaire (SGRQ). This provides three component scores: symptoms, activity and impacts scores, in addition to SGRQ total score (8). Smoking history was expressed by the number of pack-years (py). Pulmonary function was assessed by spirometry, including postbronchodilator FEV1 measuring, to confirm the diagnosis in COPD group. All subjects underwent heart rate evaluation at rest and during exercise (6-minute walk test, 6MWT). Using a polygraph (SOMNOcheck® Effort, Weinmann®, Germany), pulse rate and oxygen saturation (SpO2) were continuously recorded as follows: 6 minutes with the patient in supine position, 6 minutes in sitting position and 6 minutes during exercise (6MWT). The 6-minute walk test was performed according to the standards of American Thoracic Society (9).

The study was approved by the Ethics Committee of Iasi Clinic of Pulmonary Diseases, and the patients were enrolled only after they provided appropriate informed consent.

Data analysis was performed using Statistical Package for the Social Sciences (SPSS v.16.0.). The data were presented as mean ± standard deviation (SD). The equality of means for quantitative variables of the control and COPD groups were assessed for significance using the unpaired Student's t-test. In case the assumption of normality was not met, a nonparametric test was applied (Mann–Whitney U-test). Analysis of variance (ANOVA) was used to test the means equality in case of more than two samples. The Pearson correlation coefficient or the Spearman rank correlation coefficient was calculated to assess the

relationships between various clinical and functional parameters in COPD patients. All statistical tests were 2-tailed, and p values < 0.05 were considered significant for all analyses.

RESULTS

We enrolled a total of 32 patients in the COPD group and 29 subjects in the control group. The COPD group had a higher smoking index and a lower body mass index than the control group. The 6-minute walking distance was significantly higher for the control group (tab. I).

Regarding pulse rate, both case and control groups shared a similar trend, the mean values significantly increasing from supine to sitting position and from sitting position to exercise during 6MWT ($p<0.001$ for both COPD and control groups). The results demonstrate significantly higher pulse rate mean values in COPD subjects than in controls, during rest as well as during exercise: supine position, sitting position and 6-minute walk test, respectively (tab. II, fig. 1). However, no significant differences were found between study groups in pulse rate increase (mean pulse rate differences) from supine to sitting position ($p=0.479$) and from sitting position to exercise during 6MWT ($p=0.065$).

TABLE I

Anthropometric, clinical and respiratory functional characteristics in the study groups

	COPD			**Control**			
Subjects n	n=32			n=29			
	Mean ± SD	**Min**	**Max**	**Mean ± SD**	**Min**	**Max**	**p value**
Age yrs	65.75 ± 8.79	51.0	85.0	61.72 ± 8.51	48.0	80.0	0.068
Weight kg	68.09 ± 17.48	45.0	110.0	83.37 ± 15.93	58.6	125.0	<0.001
Height cm	168.59 ± 7.27	154.0	192.0	171.17 ± 5.75	159.0	180.0	0.133
BMI $kg \cdot m^{-2}$	23.81 ± 5.18	17.6	38.1	28.37 ± 4.79	20.5	43.3	<0.001
Smoking py	38.64 ± 19.43	10.0	100.0	17.96 ± 20.13	0.0	80.0	<0.001
MMRC	2.28 ± 0.95	1	4	-	-	-

FEV1/FVC	52.6 ± 11.1			80.7 ± 7.3			<0.001
6MWT m	281.4 ± 107.5			426 ± 77.4			<0.001

TABLE II

Mean pulse rates - comparison between COPD and control groups

	COPD			**Control**			
Subjects n	n=32			n=29			
Pulse rate $beats \cdot min^{-1}$	Mean ± SD	Min	Max	Mean ± SD	Min	Max	p value
Supine	78.16 ± 16.61	52.2	111.3	66.42 ± 8.57	51.2	87.9	0.001
Sitting	82.87 ± 17.03	52.7	115.4	71.49 ± 8.88	53.8	92.4	0.002
6MWT	97.07 ± 2.36	90.1	103.3	90.6 ± 2.39	80.0	96.9	<0.001

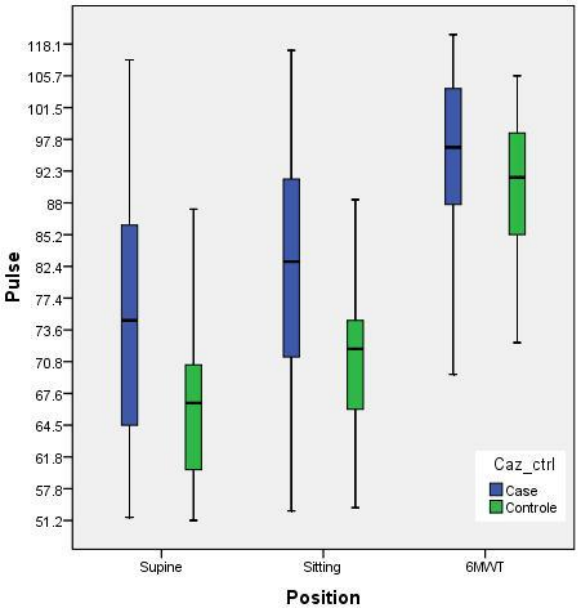

Fig. 1. The trend of pulse rate in the study groups

Even if pulse rate increase seems to be higher in controls than in COPD group as a result of the transition from rest to exercise (6MWT), the difference was on the borderline of statistical significance. The resting pulse rate (mean pulse rate for supine position) and peak pulse rate (maximum value during 6MWT) were assessed, the calculated difference between peak rate and resting rate representing the chronotropic response to exercise. The chronotropic peak moment was determined as the time of the peak in pulse rate during the 6 minute period of walk test. The chronotropic response and the chronotropic peak moment did not show significant differences between COPD and control groups (tab. III).

TABLE III

Chronotropic response – comparison between COPD and control groups

	COPD	**Control**	
Subjects n	n=32	n=29	
Pulse rate variation beats·min^{-1}	**Mean ± SD**	**Mean ± SD**	**p value**
Supine to sitting	4.71 ± 8.49	5.07 ± 4.6	0.479
Sitting to 6MWT	14.25 ± 8.58	19.1 ± 11.47	0.065
Chronotropic response (beats·min^{-1})			
	55.19 ± 30.93	57.21 ± 26.39	0.686
Chronotropic peak moment (sec)			
	173.9 ± 114.7	181.9 ± 111.3	0.783

We searched for potential determinatives of pulse rate alterations in COPD patients, assessing the relation of this parameter with other clinical or functional parameters (tab. IV). The mean pulse rate during 6 minute walk test inversely correlated with mean SpO2. In COPD patients, SpO2 demonstrated an opposite trend than pulse rate in relation with exercise, significantly decreasing during walk test as compared with rest in supine position (p=0.019). However, we did not find other correlations between pulse rate alteration, either during rest or exercise, and any other functional or clinical parameter in COPD patients, including MMRC dyspnea score, FEV1 and SGRQ scores. Resting pulse rate seems to determine the pulse rate increase during exercise, 6MWT mean pulse rate strongly correlating with mean pulse rates for both supine and sitting position (p<0.001).

TABLE IV

Potential determinatives for the pulse rate alteration in COPD group

		Correlation coefficient r	p value
Supine pulse rate	Sitting pulse rate	0.871	<0.001
Supine pulse rate	6MWT pulse rate	0.701	<0.001
Sitting pulse rate	6MWT pulse rate	0.819	<0.001
6MWT pulse rate	6MWT SpO2	-0.354	0.047

DISCUSSION

COPD associates an important risk of cardiovascular disease, the factors responsible for this association remaining largely unknown. Elevated resting heart rate was proved to be a strong independent risk factor for cardiovascular diseases in healthy subjects (10).

Our results have proved a significantly higher resting heart rate in COPD patients compared with controls without lung disease, for either supine or sitting position. Jensen et al. showed that resting heart rate was associated with cardiovascular mortality in a study including 16,696 COPD patients. They also found a strong association of the resting heart rate with COPD severity assessed as airway obstruction (11). We did not find any association between resting heart rate and FEV1 percent of predicted value (p=0.54), probably because of the small size of our study group. Furthermore, Van Gestel et al. found a significant correlation between resting heart rate and exercise capacity assessed by 6MWT distance (12). Our study did not prove any association between resting heart rate and health impairment measured by SGRQ in COPD patients in either symptoms, activity, impacts, or total scores of SGRQ. Dyspnea score (MMRC) did not correlate with resting heart rate, too. The higher resting heart rate might be explain by autonomic nervous system dysfunction in COPD patients, resulting in alterations of cardiac autonomic modulation and enhanced sympathetic tone at rest (5). Hypoxemia seems to be one of the determinant factors of this dysfunction, given the effect of oxygen supplementation which significantly and favorably alters autonomic modulation in COPD (13). There are also studies which obtained divergent results. Chen et al. found that resting autonomic nervous function of COPD patients is not different from that of normal controls.

The airway obstruction was not related

to the cardiac autonomic nervous function, but a worse oxygenation status was associated with increased cardiac vagal and decreased cardiac sympathetic activities in COPD patients (14).

Most of the researches regarding resting heart rate in COPD have assessed the patients in supine position. However, the transition from supine to sitting position is proved to improve hemodynamics, to decrease the respiratory functional residual capacity and airflow limitation, and to allow the accessory muscle use in breathing (15). These functional mechanisms which explain the orthopnea in COPD as well as in heart failure may also result in autonomic modulation and consequently in heart rate modulation. We found a significant increase in heart rate determined by transition from supine to sitting position in COPD patients. The heart rate increase in COPD patients was similar with the heart rate increase in healthy subjects (4.71 beats/minute and 5.07 beats/minute, respectively). However the mean heart rate for sitting position was significantly higher in COPD patients than in the control group subjects, maintaining the same trend as in supine position. The exercise represented by 6MWT determined a similar chronotropic response in COPD group compared with control group (55.19 beats/minute and 57.21 beats/minute, respectively). However, the mean heart rate during exercise was significantly higher in COPD patients than in controls, maintaining the same trend as at rest. The mean time for chronotropic peak reaching, within the 6 minute period was also similar in COPD and control groups (173.9 seconds and 181.9 seconds, respectively). Our results on heart rate assessment during exercise are different from the results obtained by Inal Ince et al. They found a peak heart rate and chronotropic index significantly lower in COPD patients than in healthy subjects ($p<0.05$). Other interesting finding in their study was the relation between chronotropic response, BMI, and dyspnea score (MMRC), respectively. Weight and body mass index were significantly higher than in COPD patients with normal chronotropic response ($p<0.05$). MMRC dyspnea score explained 44% of the variance in chronotropic index (16). We did not find any correlations between chronotropic response and functional or clinical parameters in COPD patients, including MMRC dyspnea score, FEV1 and SGRQ scores. However, we determined the chronotropic response during a submaximal exercise test (6MWT), unlike the study by Inal Ince et al. who used incremental exercise testing, although the COPD group in their study included only 25 patients.

The results obtained by Bartels et al. suggest that cardiac autonomic modulation is altered in patients with COPD during maximal exercise. Autonomic changes were not significantly correlated with age, gender, body mass index, spirometry, lung volumes, resting gas exchange, or oxygen saturation during exercise (17). In our study, oxygen saturation and resting pulse rate seem to be the only possible determinatives of pulse rate increase during submaximal exercise, strongly correlating with the mean pulse rate during 6MWT.

CONCLUSIONS

COPD associates elevated pulse rates during both rest and exercise. Pulse rate increasing in transition from supine to sitting position and chronotropic response during exercise are similar in COPD and healthy subjects. Hypoxemia and resting pulse rate are determinatives of chrono-

tropic response during exercise in COPD patients. Pulse rate alterations do not correlate with airway obstruction, dyspnea, or health impairment in chronic obstructive lung disease. Although more data are needed, elevated heart rate associated during both rest and exercise might result in increased cardiovascular risk in COPD.

THE ROLE OF RIFAXIMINE IN THE PREVENTION OF THE SPONTANEOUS BACTERIAL PERITONITIS

THE ROLE OF RIFAXIMINE IN THE PREVENTION OF THE SPONTANEOUS BACTERIAN PERITONITIS (Abstract): Cirrhosis is characterized by an increased susceptibility to infection. Spontaneous bacterial peritonitis (SBP) is the most common infectious complication, the main causes being the bowel bacterial overpopulation, the increased intestinal permeability and bacterial translocation. Antibiotic prophylaxis with Norfloxacin increases the rate of PBS with G+ multiresistant bacteria. **Purpose**: to demonstrate the advantage of using rifaximin, nonresorbable broad spectrum antibiotic, in SBP prophylaxy. **Material and methods**: The study is a prospective case-control, which included 46 patients diagnosed with Child class C cirrhosis and refractory ascites, based on clinical, biological, ultrasound and endoscopic findings, followed over a period of 6 months. Protein level in ascitic fluid (AF) was higher 14g/dl. SBP was defined as the presence of > 250 PMN/mm^3. Patients were divided into 2 groups, group 1 comprised 22 patients who received rifaximin treatment during the study for a previous episode of hepatic encephalopathy (HE), and group 2 consisted of 24 patients who did not receive antibiotic treatment during follow-up. **Results**: Rifaximin significantly decreases the polymorpho-nucleares (PMN) in ascitic fluid from patients, one single case of neutroascitic SBP with negative cultures were recorded in this group, with a net improvement of the general condition. In group 2 who did not follow any antibiotic treatment, SBP was recorded in 4 patients, an increase of PMN in ascitic fluid at 14 patients, an approximately constant value in 4 patients, a decrease in 2 subjects. **Conclusions**: The study suggests that rifaximin causes a significant decrease in PMN in AF, producing a decrease in SBP frequency and improvement of life in cirrhotic patients with refractory ascites. In this study, the effects of rifaximin on intestinal bacterial overpopulation and bacterial translocation, decisive factors in SBP, are consistent with literature data. Use of rifaximin as an alternative method to prevent SBP deserves more attention. **Keywords**: SPONTANEOUS BACTERIAL PERITONITIS, BACTERIAL TRANSLOCATION, PROPHYLAXY TREATEMENT, RIFAXIMIN.

Cirrhosis is characterized by an increased susceptibility to infection. In this way, spontaneous bacterial peritonitis (SBP) is a major complication of liver cirrhosis, the incidence in hospitalized patients with ascitic cirrhosis ranging between 7% and 23%, but increased when ascites associated low protein concentration (below 1g/100 ml)

and severe hepatic impairment (1).

In most cases, SBP is a monomicrobial infection, the culture of the ascitic fluid reveals a single microorganism, and the neutrophils being above 250/mm^3. The essential pathogenic elements are the intestinal bacterial overpopulation, bacterial translocation, increased intestinal permeability and immune deficiency.

Translocation of bacteria is defined as the passage of viable bacteria from the gastrointestinal tract to extra-intestinal sites, such as mesenteric lymph nodes (MLN), liver, spleen, kidneys, and blood flow. Overgrowth of the intestinal gram-negative bacilli will be followed by translocation in mesenteric lymph nodes, in the conditions of disruption of the intestinal barrier (2). Unlike the aerobic bacteria, which translocate through an intact mucosa, the anaerobic bacteria translocate through an intestinal mucosa defect (3). In fact, by eliminating the anaerobic bacteria, the intestinal bacterial overgrowth is facilitated, which one of the main factors is promoting bacterial translocation (4).

The long term prognosis of patients with SBP is unfavorable, the recurrence rate being 43% at 6 months. Despite the use of empirical antibiotic therapy, particularly cefotaxime, as well as antibiotic prophylaxis, currently mortality ranges from 10-30% (5).

A recent study shows that 30.8% of patients with Child class C cirrhosis, who did not have antibiotic treatment, have enteric bacteria in the mesenteric lymph nodes, while only 4.5% of those who were treated for decontamination have an enteric bacterial population in the mesenteric lymph nodes (6). Induced antisecretory hypochlorhydria favors the intestinal bacterial overgrowth. In patients with liver cirrhosis there is an intestinal motility disorder, which promotes intestinal bacterial overpopulation.

An important problem which has been recently discussed is the prophylactic treatment of spontaneous bacterial peritonitis with Norfloxacin (400 mg orally every 12 hrs.) considering the possibility to select quinolone-resistant bacteria species. However, special attention and a high degree of suspicion should be maintained in patients with spontaneous bacterial peritonitis that followed the prophylactic treatment. If the standard treatment fails, a 48h control paracentesis should be associated with vancomycin and imipenem (7).

Since 1994, investigators have explored the possibility of resistant bacteria species in patients receiving norfloxacin 400 mg daily to prevent SBP (8). By observing quantitative stool cultures of 31 patients, no resistant organisms were isolated from 15 patients, however, fluoroquinolone-resistant organisms were isolated from 16 patients between days 14 and 43, inclusive *Staphylococcus spp aureus* coagulase-negative, *Citrobacter freundii, Enterobacter cloacae, Klebsiella oxytoca*, and *Proteus rettgeri*.

In this way, considering that antibiotic prophylaxy of SBP with Norfloxacin increases the G+ multiresistant bacteria, the aim of the present work was to proove the advantage of using rifaximin, non-resorbable broad-spectrum antibiotic in SBP prophylaxis.

MATERIAL AND METHODS

The study is a prospective case-control, which included 46 patients diagnosed with Child class C cirrhosis and refractory ascites, based on clinical, biological, ultrasound and endoscopic findings, followed

over a period of 6 months. Patients were divided into 2 groups, group 1 comprised 22 patients who received rifaximin treatment during the study for a previous episode of hepatic encephalopathy, and group 2 consisted of 24 patients who did not receive antibiotic treatment during follow-up. Protein level in Af was higher than 1.4 g/dl. SBP was defined as the presence of > 250 PMN/mm^3. Diagnostic paracentesis was done with white blood cells (WBC) and PMN counting, and biochemical determinations (proteins, glucose). Cultures of the AF have also been done.

Our data were statistically analyzed by using one-way analysis of variance (ANOVA). All results are expressed as mean ± SEM. F values for which $p<0.05$ were regarded as statistically significant.

RESULTS

Regarding the distribution of the PMN values, as a result rifaximin administration for 6 months, we could observe that a high percentage of the treated patients manifested a decrease in their levels of PMN (20 patients out of 22 ~ 90 %). Also, only one cases each, for stable PMN and SBP (5 %) is reported for this group (fig. 1)

When analyzing the changes observed after 6 months in the untreated group, we observed that most of the patients (58 %) experienced an increase in their levels of PMN, with only 8 % of them having decreased number of PMN and 17 % each for stable values of their PMN or SBP (fig. 2).

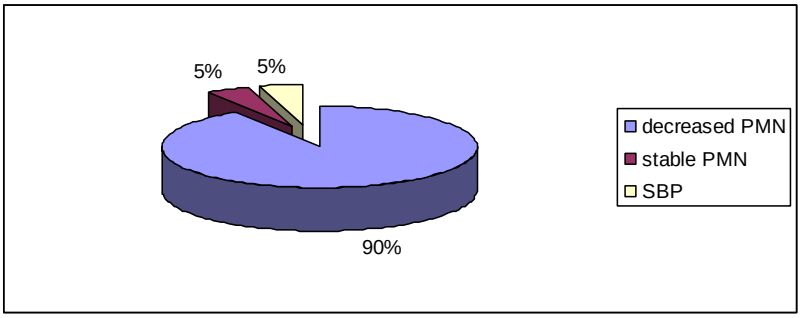

Fig. 1. The percentage distribution of the PMN values, after 6 months of rifaximin administration

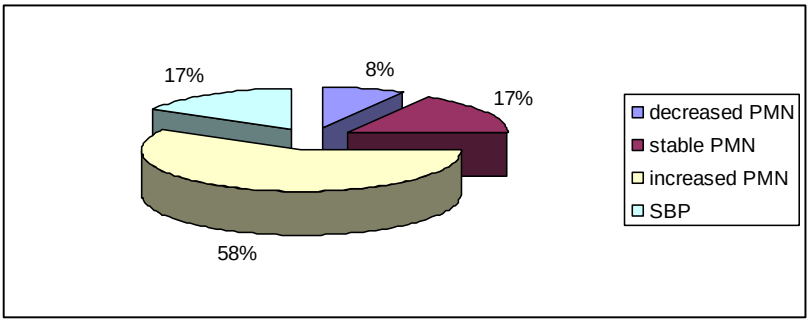

Fig. 2. The percentage distribution of the PMN values, after 6 months, in the untreated patients

Table I presents the detailed average values for the PMN levels at the baseline point, as well as after 6 months, in both our study groups (treated vs. untreated) (tab. I). We could observe a significant difference (F(1.42)=6, p=0.022) between the baseline point and after 6 months of treatment in our group of patients treated with rifaximin. Conversely, there were no significant differences (F(1.46)=1, p= 0.066) between baseline levels and after 6 months levels in the group of untreated patients, as shown by ANOVAs One Way (tab. I).

TABLE I

The PMN values, at the baseline point and after 6 months, in treated and untreated patients

	Treated			Untreated		
	Baseline	**6 months**	**p**	**Baseline**	**6 months**	**p**
PMN	101.09 ± 8.67	62.5 ± 13.82	0.022	54.41 ± 7.41	104.33 ± 20.41	0.066

Moreover, our final analysis focused on the possible differences between groups of patients after 6 months (treated vs. untreated). As can be seen in the Figure 3, we observed an increase of the PMN values in the untreated group, when compared with patients treated with rifaximin (F (1.44) =3, p=0.1) (fig. 3).

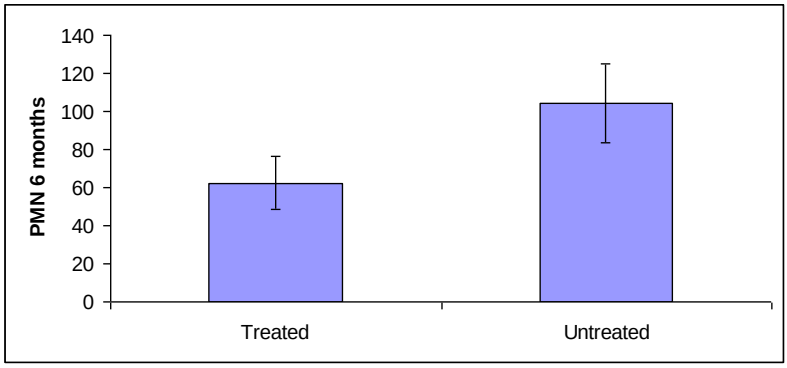

Fig. 3. PMN values after 6 months, in patients treated with rifaximin vs. untreated group

DISCUSSION

The present study demonstrated that rifaximin is associated with a significant decrease of PMN in the ascitic fluid, which could suggest that it could be implicated in the decrease of SBP frequency, and also in improving the quality of life in cirrhotic patients with refractory ascites.

These aspects could be very important considering that rifaximin, nonresorbable broad-spectrum antibiotic, has less adverse effects and does not increases the G+ multiresistant bacteria.

Cirrhotic patients have frequent episodes of infections due to immunodeficiency and malnutrition, which justifies prophylactic antibiotic treatment. Establishing the optimal therapeutic dose should

avoid the selection of multiresistant bacteria (9).

Among hospitalized patients, it was found that 16% had a multidrug-resistant bacteria, (most often Staphylococcus), mostly those who received prior antibiotic treatment. Germs are often 10 times more aggressive in 33% of cases, resulting a longer hospitalization period and also increased hospital mortality (10).

A direct relationship between micro biota composition and bacterial translocation was demonstrated in mice. Bacterial overgrowth that occurs in cirrhosis due also to the intestinal hipomotility was correlated with bacterial translocation, endotoxemia and the development of spontaneous bacterial peritonitis (11).

Authors warned against antibiotiotic profylaxis in patients with cirrhosis. Subsequent studies have shown changes in the epidemiology etiology associated with PBS antibiotic prophylaxis (11).

In consideration of two time periods (1991-1995 and 1996 2000), Singh et al. have shown that the incidence of SBP with multidrug-resistant organisms in patients who were admitted in a liver transplant unit increased from 8.3% to 38.5%, the most resistant pathogens (71%) were either ESBL -producing organisms and methicillin-resistant *S. aureus* . The researchers noted that asymptomatic colonization of the gastrointestinal tract with ESBL-producing organisms normally precedes the symptoms. With the occurrence of gram-positive methicillin-resistant (MRSA) and gram-negative ESBL-producing germs, it seems prudent to evaluate patients with resistant pathogens SBP. (12). Thus, if patients who have received prior fluoroquinolones as SBP prophylaxy do not respond to empiric treatment after 48 hours, vancomycin (Vancocin, Viro Pharma) should be added to the treatment. Local epidemiological results also support the transition to antibiotics such as ertapenem (Invanz) or tigecycline (Tigacil). (12, 13).

In a recent study, it was demonstrated that in the cirrhotic patients which were not treated with fluoraoquinolone , the dominant spectrum in the ascitic fluid is represented by gram-negative bacteria (67%), whereas in those treated the dominate germs were gram positive bacteria. (14)

Given the increased cost and risk of developing resistant organisms, antibiotic prophylaxis is indicated in the following three groups: the history of SBP, those hospitalized for upper gastrointestinal bleeding and those with low-protein-concentration in AF.

Selective decontamination by prophylactic antibiotic aims to reduce the bacteria from the gastrointestinal tract in order to reduce the risk of developing spontaneous bacterial peritonitis.

Also, a recent study by Kalambokis et al. (15) demonstrated that administration of a therapy for four weeks with rifaximin 1.200 mg / day significantly reduced the number of neutrophils in the ascites fluid of cirrhotic patients with sterile ascites, in accordance with a significant decrease in plasma endotoxin. The observations are consistent with recent findings that show a significantly reduced rate in developing SBP after 5 years in cirrhotic patients receiving rifaximin.

CONCLUSIONS

The present study suggests that rifaximin cause a significant decrease in PMN in AF, causing a decrease in SBP frequency and improvement of life in cirrhotic patients with refractory ascites. In this study,

the effects of rifaximin on intestinal bacterial overpopulation and bacterial translocation as decisive factors in SBP, are consistent with literature data. Therefore the use of rifaximin as an alternative method to prevent SBP deserves more attention.

BODY COMPOSITION ALTERATIONS IN CHRONIC OBSTRUCTIVE PULMONARY DISEASE (Abstract): Metabolic disorders are involved in the pathogenesis of some co morbid conditions such as atherosclerosis and cardiovascular diseases, which frequently occur in COPD patient. These disorders may also associate alterations in body composition. **Aim:** To determine the particularities of body composition, assessing its relationship with respiratory function and clinical status in COPD patients. **Material and methods:** A prospective case-control study including 31 patients with COPD admitted to the Clinic of Pulmonary Diseases Iasi from April 2011 to September 2012, and 29 subjects without lung diseases which served as controls. Body composition (body fat, lean body mass, body water) and basal metabolic rate were measured using bioelectrical impedance analysis. Other assessments included anthropometric parameters, spirometry, 6-minute walk test. In COPD patients, dyspnea scale and health impairment assessment by St George's Respiratory Questionnaire (SGRQ) were used. **Results:** In COPD group, 67% of the patients were normal weight, 10% underweight, 10% overweight and 13% obese. The results showed that lean body mass ($p<0.001$), dry lean mass ($p<0.001$), total body water ($p<0.001$) and basal metabolic rate ($p<0.001$) were lower in the COPD patients as compared to the controls. These findings significantly correlate with age, dyspnea, severity of airway obstruction and exercise capacity in patients with COPD. No significant differences between study groups were observed in body fat mass. **Conclusions:** Lean body mass, dry lean mass, and total body water are altered in COPD patients and significantly correlate with age, clinical and functional severity of COPD. **Keywords:** COPD, BODY COMPOSITION, FAT MASS, LEAN MASS.

Chronic obstructive pulmonary disease (COPD) is associated with an increasing prevalence and a high mortality in the coming decades, being a challenge for the clinicians and a leading public health problem worldwide (1). One of its specific features associated with increased morbidity and mortality is the presence of chronic co morbidities. The complex pathogenic link between COPD and co morbidities seems to involve systemic inflammation which represents another important feature of COPD (2).

The metabolic syndrome is frequently diagnosed in overweight COPD patients, its association with increased systemic in-

flammation independent of lung function impairment being thus proved (3). However, data on metabolic alteration in COPD are still poor and inconsistent. The "obesity paradox", defined as an inverse association of good health, survival and obesity in COPD patients was described. A higher mortality was found among underweight COPD patients, whereas overweight patients had a lower overall mortality (4). Other researchers have found a low fat-free mass frequently associated in COPD patients, even when body mass index (BMI) was normal. Furthermore, low fat-free mass is considered an independent predictor of mortality in COPD (5).

Plasma adiponectin, an adipose tissue-derived specific protein with anti-inflammatory and anti-atherosclerotic effects, correlates with body weight loss and systemic inflammation in COPD, some researches concluding that adiponectin may reduce cardiovascular events in underweight patients (6).

However, cardiovascular diseases, many of these involving atherosclerosis and metabolic disorders, represent an important comorbidity accounting for 26% of the cause-specific mortality in COPD patients (7).

COPD patients have excessive visceral fat even in advanced stages of the disease despite the absence of obesity (8). Physical inactivity, a commonly observed feature in COPD, might be a determinant of visceral fat accumulation (9).

Given the pathogenic and prognostic implications of fat mass alteration, our study aimed to determine the particularities of body composition, including fat body mass, lean body mass, body water and basal metabolism, in view of assessing their relationship with respiratory function and clinical status in COPD patients.

MATERIAL AND METHODS

We conducted a prospective case-control study in which we determined and compared body composition in patients with COPD and subjects without lung disease. The study included patients admitted to the Clinic of Pulmonary Diseases Iasi in the interval April 2011 - September 2012, diagnosed with COPD according to the criteria of Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines: chronic dyspnea, cough, or sputum production, and persistent airflow limitation, confirmed by spirometry (a ratio of forced expiratory volume in 1 second (FEV1) to forced vital capacity (FVC) of <0.7 after bronchodilator administration) (1).

The control group included subjects with no history of lung diseases, clinical symptoms suggestive of COPD or respiratory dysfunction, based on the results of pulmonary function tests. COPD patients and controls were matched for sex and age. Male gender and age between 45 and 85 years were inclusion criteria for both COPD patients and controls. Cachexia was the exclusion criterion for the control group.

The study was approved by the Ethics Committee of the Clinic of Pulmonary Diseases Iasi and the patients were enrolled only after they provided appropriate informed consent.

The study protocol included the clinical and anthropometric assessment of the subjects: body height and weight were measured and BMI was calculated as weight/height^2 (kg/m^2). We used the World Health Organization classification of BMI which categorizes BMI into the following categories: underweight (BMI$\leq$18.5 kg/m^2), normal weight (BMI: 18.5-24.99 kg/m^2), overweight (BMI: 25-29.9 kg/m^2), and

obesity (BMI>30 kg/m^2) (10). Smoking history was expressed as the number of pack-years (py). For the COPD group the degree of dyspnea was estimated using the Modified Medical Respiratory Council (MMRC) dyspnea scale (11).

Pulmonary function was assessed by spirometry, including post bronchodilator FEV1 measuring, to confirm the diagnosis of COPD in the corresponding group. FEV1 was expressed as percentage of predicted value. Exercise capacity was assessed in all subjects by the 6-minute walk test (6MWT). This was performed according to the standards of the American Thoracic Society (12). Health impairment in COPD patients was measured by St George's Respiratory Questionnaire (SGRQ). This provides three component scores: symptoms, activity, and impacts, in addition to SGRQ total score (13). Body composition was measured using bioelectrical impedance analysis with BodyStat 1500 analyzer (Bodystat Ltd, Douglas, Isle of Man). The device measures/estimates the following parameters: body fat percentage and fat weight (kilograms), lean mass percentage and lean mass (kilograms), body water percentage and total body water (liters), basal metabolic rate (kilocalories), and body impedance.

For analysis data were expressed as mean ± standard deviation (SD). Quantitative variables were compared using the unpaired Student's t-test. When the assumption of normality was not met, a nonparametric test was applied (Mann–Whitney U-test). Pearson correlation coefficient or Spearman rank correlation coefficient were calculated to assess the relationships between various clinical and functional parameters in COPD patients. All statistical tests were 2-tailed, and p value < 0.05 was considered significant for all analyses.

RESULTS

We enrolled a total of 60 male subjects, of which 31 were COPD patients and 29 controls. The most important clinical and anthropometric characteristics, respiratory function and body composition data are shown in table I.

TABLE I

Clinical characteristics, respiratory function and body composition

	Case	Control	p value
Age (years)	65.77 ± 8.86	61.41 ± 8.69	0.056
Smoking (py)	37.95 ± 18.83	19.34 ± 20.23	<0.001
Weight (kg)	66.80 ±16.27	81.51 ± 16.45	<0.001
Height (cm)	168 ± 6.11	171.34 ± 6.00	0.061
BMI (kg/m^2)	23.57 ± 5.09	27.74 ± 5.26	0.001
FEV1 (%)	37.59 ± 13.47	102.28 ± 15.02	<0.001
FEV1/FVC (%)	51.87 ± 10.90	80.95 ± 7.43	<0.001
6MWT distance (m)	276.09 ± 106.68	424.2 ± 77.9	<0.001
Fat (%)	17.89 ± 8.70	18.10 ± 7.24	0.842
Fat (kg)	12.83 ± 8.11	15.45 ± 9.24	0.185
Lean (%)	81.92 ± 8.56	81.89 ± 7.24	0.750
Lean (kg)	54.44 ± 11.21	66.22 ± 10.56	<0.001
Dry lean (kg)	8.35 ± 5.50	12.86 ± 4.33	0.001
Water (%)	70.60 ± 11.19	66.48 ± 8.2	0.111
Water (L)	46.09 ± 7.08	53.15 ± 6.86	<0.001
Basal metabolism (kcal)	1626.8 ± 290.9	1915.8 ± 262.9	<0.001
Impedance	410.8 ± 69.1	357.1 ± 57.2	0.002

A higher smoking index and lower weight were found in the COPD as compared to the control group. The 6-minute walking distance was significantly higher in the control group. BMI calculation in the patients in the COPD group showed: 67% were normal weight, 10% underweight, 10% overweight and 13% obese (fig. 1).

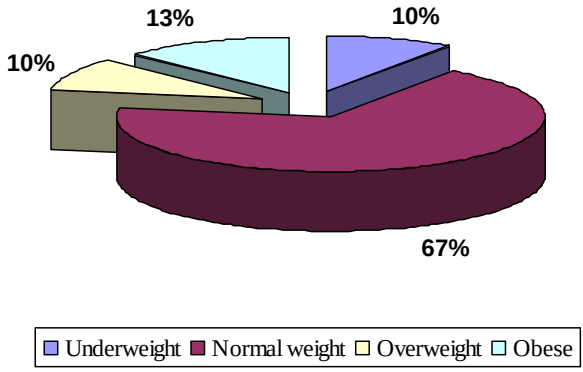

Fig. 1. Distribution of COPD patients according to BMI

The results of body composition assessment revealed certain particularities in COPD patients. The dry lean mass was significantly lower than in the healthy subjects. The absolute lean mass value, expressed in kilograms, was also lower in COPD patients, but no significant differences in percentage values between the two study groups were found.

Body water, in liters, was higher in the control compared with COPD group. However, body water percentage was higher in COPD patients than in controls, without reaching statistical significance. No difference in body fat mass, expressed either as percentage or absolute value, between COPD patients and healthy subjects was found. The different patterns of body composition determined a significant difference in body impedance between the study groups, which was significantly higher in COPD patients. Bioelectrical impedance analysis allowed the estimation of the basal metabolic rate. This was significantly higher in the control group than in COPD patients.

We also assessed the relationships between the results of body composition analysis and other clinical or functional parameters in COPD patients (tab. II).

In COPD patients, lean mass and dry lean mass, expressed in kilograms, were inversely correlated with age and dyspnea score (MMRC), and positively correlated with FEV1 and 6MWT distance (6MWTd). Body water percentage correlated with age and water volume (liters), inversely correlated with dyspnea score and positively correlated with FEV1 and 6MWTd. Basal metabolic rate, determined by bioelectrical impedance analysis, inversely correlated with age and MMRC and positively correlated with FEV1 and 6MWTd. No significant correlations between body composition components and health impairment in COPD patients, estimated by the three SGRQ component scores including symptoms, activity and impacts were found.

TABLE II

Correlations between body composition, clinical and functional parameters in COPD patients

		Age	MMRC	FEV1%	FEV1/FVC	6MWTd
Lean (kg)	Correlation Coefficient	-0.395	-0.473	0.47	0.475	0.505
	p value	0.002	<0.001	<0.001	<0.001	<0.001
Dry lean (kg)	Correlation Coefficient	-0.523	-0.398	0.361	0.402	0.474
	p value	<0.001	0.002	0.005	0.001	<0.001

	p value	0.004	<0.001	<0.001	<0.001	<0.001
Impedance	Correlation Coefficient		0.392	-0.42	-0.34	-0.318
	p value		0.002	0.001		0.013

DISCUSSION

Even though the majority (67%) of COPD patients had a BMI within normal limits, the subjects in the control group presented a significantly higher BMI, which is in line with the results reported by Engelen et al. in patients with pulmonary emphysema (14).

Unlike Ischaki et al. we have proved a significant correlation of BMI, not only with 6MWTd but also with FEV1 which is the main determinant of COPD stage (15). A major difference is that, unlike previous studies, we found no differences in body fat mass between COPD patients and healthy controls and no correlation between body fat mass and clinical or functional parameters (8).

Ischaki et al. have demonstrated correlations between free-fat mass index and MRC dyspnea scale, 6MWT distance and percentage predicted FEV1 (15). Our results support these findings, proving an inverse correlation between lean mass/dry lean mass, expressed in kilograms, and dyspnea score (MMRC) and a positive correlation with FEV1 and 6MWTd. We also found a significantly lower lean mass in the COPD than in the control group.

Body water was also significantly lower in COPD patients than in healthy subjects. As lean body mass, body water inversely correlated with dyspnea score and positively correlated with FEV1 and 6MWTd. Previous researches demonstrated that COPD patients associating fat-free mass depletion are characterized by increased extracellu-

lar/intracellular water ratio (16).

Body impedance analysis also provided an estimation of the basal metabolic rate. This was lower in COPD group, inversely correlated with age and dyspnea severity and positively correlated with FEV1 and exercise capacity. However, other researchers have used more accurate methods for assessing metabolic rate in COPD. Using indirect calorimetry adjusted for the influence of fat-free mass, Creutzberg et al. have proved that hypermetabolism commonly occurs in COPD but cannot be linked to aging and fat-free mass depletion (17).

CONCLUSIONS

Although more than a half of our COPD patients are normal weight, they may present important disturbances in body composition. Lean body mass, dry lean mass and body water are significantly lower in COPD patients than in healthy subjects. These significantly correlate with age, dyspnea, severity of airway obstruction, and exercise capacity in patients with chronic obstructive lung disease.

NEWS

INCREASED RISK OF ACUTE PANCREATITIS BY ORAL CORTISONE TREATMENT

Acute pancreatitis is a common disease of the pancreas favored by the lithiasis, smoking, consumption of alcohol and medication, such as oral cortisone used to treat asthma and autoimmune diseases. In 15% of cases, the disease can threaten the patient's life. Into a recent study Dr Omid Sadr-Azodi and colleagues demonstrated the relationship between administration of cortisone and acute pancreatitis. The results show that treatment with oral cortisone determined a 70 percent higher risk of developing acute pancreatitis. The researchers found that the risk of acute pancreatitis was highest 4 to 14 days after drug dispensation and attenuated thereafter. Also, the people who used aerosol cortisone have not manifested an increased risk for acute pancreatitis. They concluded that the current oral glucocorticoid use is associated with an increased risk of acute pancreatitis (Sadr-Azodi O, Mattsson F, Sjöberg Bexelius T et al. Association of Oral Glucocorticoid Use With an Increased Risk of Acute Pancreatitis. A Population-Based Nested Case-Control Study. *JAMA Intern Med.* 2013;():1-6. doi:10.1001/jamainternmed.2013.2737).

IMPACT OF CLOPIDOGREL RESPONSE ON THE CLINICAL EVOLUTION IN PATIENTS WITH ACUTE CORONARY SYNDROMES (Abstract): **Aim:** the purpose of the present study was to determine the relationship between the Clopidogrel genetic response (based on laboratory specific tests) and the worse evolution of the patients with acute coronary syndromes. **Material and methods:** The study included 80 patients (11 females and 69 males), aged between 45 – 85 years, admitted in the 1st Department of Cardiology, between January – June 2012, diagnosed with acute coronary syndromes (especially unstable angina). All the patients received Clopidogrel as antiplatelet agent, in some cases associated with aspirin. The diagnosis of acute coronary syndrome was based on clinical, ECG, echocardiographic and enzymatic signs. All the patients accepted to be included in the present study and signed a consent formulary. The Clopidogrel resistance was determined by specific genetic laboratory tests. **Results and discussion:** Of 80 cases, 4 patients were identified as normal responders (5%), 3 patients were low responders (3.75%), 58 patients were high responders (72.5%) and 15 patients were unpredictable (18.75%). In the high responders' group a lot of hemorrhagic disorders in different territories were identified. Normal responders had a good evolution. In patients with low response and unpredictable status the recurrence of angina and left ventricular failure as complications were frequent. **Conclusions:** The present study allowed a positive correlation between the haemorrhagic events and the high responder status to Clopidogrel. Low responder patients or those with an unpredictable phenotype had a worse evolution caused by the recurrence of angina or left ventricular failure. **Keywords:** CLOPIDOGREL, GENETIC RESISTANCE, ACUTE CORONARY SYNDROMES.

The concept of resistance to Clopidogrel dates a few years ago and has two implications: a clinical one, related to the unfavorable evolution and prognosis of some of the patients with acute coronary syndromes (ACS) and a second one, with practical implications, that enforces introduction on the market of some new antiplatelet agents, without the resistance phenomenon mentioned above (1, 2, 4, 6, 14).

Recent studies have shown that approximately 31% of the patients with ACS present resistance to Clopidogrel, defined as a weak response concerning platelet clotting, this category of patients having an unfavorable clinical evolution and prognosis.

Patients with early intrastent thrombosis are included in this category (3, 8, 11).

Of the liver enzymes involved in this process, a key role is held by CyP2C19 cytochrome, which has many different isoforms responsible for the variation of its catalytic activity (5, 7, 9, and 10). These variations of the catalytic activity determine variations of the conversion process of Clopidogrel into active metabolites (12, 13). According to the Clopidogrel conversion speed, patients could be slow or rapid metabolizes. Thus, some patients could have hypo response concerning the blocking of platelet clotting (followed by increased risk of thrombosis), whereas others have hyper response (clinically expressed as high hemorrhage risk) (15, 16, 17).

More importantly, the so-called "genetic resistance" to Clopidogrel is followed by dramatic increasing of stent thrombosis incidence in patients that receive Clopidogrel (2, 3, 5).

The study aimed to evaluate the degree in which the genetically determined response to Clopidogrel (demonstrated by specific lab tests) influences the evolution of patients with acute coronary syndromes.

MATERIAL AND METHODS

The study included 80 patients (11 females and 69 males), aged between 45 – 85 years, admitted in the 1st Department of Cardiology, between January – June 2012, diagnosed with acute coronary syndromes (in most of the cases different forms of unstable angina) that have accomplished the study inclusion criteria.

The acute coronary syndrome diagnostic criteria needed for patients' inclusion were the following ones:

- Clinical – anterior chest pain with angina characteristics that followed the criteria for unstable angina or important angina crisis;
- Paraclinical – suggestive electrocardiographical changes – subendocardic or subepicardic ischemic lesions or recent branch block associated with changes of myocardic cytolysis enzymes.

Patients with uncertain acute coronary syndrome criteria, those without Clopidogrel therapy, patients with contraindication of platelet antiagregant therapy (e.g., antecedents of hemorrhagic accidents or known hemorrhagic diatheses, previously known liver disease) as well as patients with psychiatric disorders or noncompliant ones were excluded.

The paraclinic investigation aimed to:

- Investigate associated risk factors: blood sugar, uric acid, complete lipid profile;
- Complete functional evaluation of the key organs involved in hypertensive and/or diabetic patients (renal function, electrolytes);
- Electrocardiogram 12 derivations – both for positive diagnosis of acute coronary syndrome and for diagnosis of different complications (e.g. rhythm and/or conduction disturbances), as well as for follow-up;
- Echocardiogram – 2D, M and Doppler – the following parameters were checked: LV and LA size, wall thickness (to appreciate left ventricular hypertrophy), systolic left ventricular function (expressed as ejection fraction and LV shortening), LV diastolic function, regional kinetic changes of LV, valvular regurgitation and other complications (intracavitar thrombus).

The patients were initially evaluated (at

the inclusion), following the complete check-up mentioned above. The final decision regarding study inclusion was taken after having a precise diagnosis and therapeutic scheme.

All the patients included in the study received platelet antiagregant therapy with Clopidogrel associated sometimes with Aspirin. In some cases the patients already had Clopidogrel therapy when included in the study, whereas for others Clopidogrel was started at the inclusion moment.

All the patients were previously informed about the aim of the study, those who agreed to the inclusion in the study signed an informed consent and then a blood sample was taken for DNA extraction.

Two samples of 2 ml peripheral blood were taken for every patient.

The anti-clotting agent was EDTA. The DNA extraction from integral blood was done -on the same day. Two extractions were done simultaneously, one for every sample taken.

The DNA extraction was performed using Wizard Genomic DNA Purification – Promega kit.

The extraction process followed 5 steps:

1. Red blood cells lysis;
2. White blood cells and nuclei lysis;
3. Cellular proteins precipitation;
4. Genomic DNA precipitation;
5. DNA rehydratation.

After rehydratation the DNA was quantified, aliquot and labeled in order to make a genomic DNA collection in the Molecular Biology Lab.

A part of the DNA was stored at -20°C in order to follow PCR experiments. The other samples were frozen at –80°C (long time storing).

TaqMan assay genotyping method used for the aimed SNPs is based on allelic discrimination by Real-Time PCR in TaqMan system.

Our study used specific probes for mutant alleles *2A, *3, *17 of the CYP2C19 gene versus specific probes for the wild allele, as well as probes for mutant allele 3435C>T versus wild type allele of the ABCB1 gene.

Work protocol: Amplification was done using Real Time PCR MX3005P Stratagene / Agillent termocycler.

Alongside the optimization and the performing of testing using TaqMan Assay, we have tried to identify an alternative method, at lower costs, that could discriminate alleles with more than 90% confidence and we have decided to use High Resolution Melting (HRM).

HRM is a technique that consists in the postPCR amplification analysis of the melting curves of the fragments of interest (amplicons).

In our study we have achieved HRM genotyping for all ABCB1c polymorphisms C3435T (rs1045642), CYP2C19*2 (c.G681A; rs4244285), CYP2C19*3 (c.G636A; rs4986893), and CYP2C19*17 (c.C806T; rs12248560).

RESULTS AND DISCUSSION

Our study includes a group of 80 patients (11 females and 69 males), aged 45-85 years old, admitted in the 1st Department of Cardiology, during January – June 2012, diagnosed with acute coronary syndromes (most of the cases with different forms of unstable angina) that have accomplished the study inclusion criteria.

Our study has achieved genotyping by means of the TaqMan system for all the patients and by means of HRM for 36 samples.

In the case of TaqMan genotyping, allelic discrimination is presented in Table I.

Using HRM we have got very good results (regarding amplification and results provided) for polymorphisms CYP2C19*2 and CYP2C19*17. For these polymorphisms the primers have functioned and we have got specific amplicons (without non-specific links and dimerization) and the results correlated 100% with the TaqMan genotyping. Allelic discrimination confidence exceeded 95%.

TABLE I.
Genotype frequencies for the studied genes and mutant alleles

Polymorphism	Genotype	Number of samples	Frequency
ABCB1 c.C3435T	CC	12	15%
	CT	48	60%
	TT	20	25%
	Allele T	55%	
CYP2C19*2,c.G681A	GG	62	77.5%
	GA	15	18.75%
	AA	3	3.75%
	Allele A	15.3%	
CYP2C19*3,g.-806C>T	CC	80	100%
	CT	0	0%
	TT	0	0%
	Allele T	0%	
CYP2C19*17, c.C806T	CC	4	5%
	CT	27	33.7%
	TT	49	61.25%
	Allele T	78.1%	

For alleles CYP2C19*3 and ABCB1 primers were not good enough and new steps of optimization will be needed.

Starting from the literature data, according to the genotyping variant of the studied alleles for gene CYP2C19, the patients were divided in several prediction categories:

1. *Normal metabolizer (N):* wild-type CYP2C19*2*3*17;

2. *Intermediate metabolizer (MI):* heterozygote for *2 and/or *3 and wild-type *17;

3. *Slow metabolizer (MS):* *2/*2, *2/*3, *3/*3, indifferent of also being heterozygote or homozygote for *17;

4. *Very quick metabolizer (MFR):* homozygote or heterozygote for *17 and wild-type for *2 and *3 ;

5. *Unpredictable metabolizer (MN):* heterozygote or homozygote for *17 and heterozygote for *2 and/or *3.

Thus, in our group study, we have identified 4 patients with normal metabolizer phenotype (5%), 3 slow metabolizer patients (3.75%), 58 patients with very quick metabolizer phenotype (72.5%) and 15 patients with unpredictable phenotype (18.75%). We didn't identify any patient with intermediate phenotype.

From the point of view of the clinical evolution, the 3 patients with slow metabolizer phenotype presented repeated episodes of intensified angina pain that needed

frequent admissions and revising of therapy scheme (increasing of nitrate and beta-blocker dose). One of the patients developed ischemic dilative cardiomyopathy, with dilated LV and important decrease of the ejection fraction. Two of the patients were sent to interventional cardiology services for coronarography and trans-luminal angioplasty with stent.

Of the 15 patients with unpredictable phenotype, 10 registered favorable evolution during the admission to hospital under therapy, without repetition of the angina pain and no other complications. The check-up after 3 months showed optimal clinical and functional parameters. 5 of the patients with unpredictable phenotype presented readmissions during the follow-up period due to the new angina pain with characteristics of unstable angor, fact that led to therapy scheme changing. 4 of these patients presented LV failure (cardiac asthma – 3 cases and acute pulmonary edema – 1 case). One of the patients (83 years old) presented a peripheral arterial embolus (in conditions of sinusal rhythm), that needed hospitalization in a vascular surgery service and emergency embolectomy. Favorable evolution was recorded later.

For the patients with rapid metabolizer phenotype we have recorded the following events:

- Prominent macroscopic haematuria (2 males aged 75 and 82 years respectively) – both needed change of therapeutic scheme without Clopidogrel;
- Cutaneous ecchymosis – 7 cases (4 females, 3 males);
- Cutaneous purpura – 1 female, associated with thrombocytopenia - 75,000/mm^3;
- Gum hemorrhage, independent of other causes – 2 cases of females. Bleeding stopped after excluding Clopidogrel from the therapeutic scheme.
- Superior digestive hemorrhage – melena – 1 male case in whom Clopidogrel was associated with Aspirin. No hemodynamic degradation was recorded in evolution.
- Haemoptysis – 1 male case (75 years old).

For the rest of the patients in this subgroup we didn't record hemorrhagic events during the follow-up period, but 15 patients needed readmission due to the aggravation of the pectoral angina (6 patients) and for left ventricular failure phenomena (12 patients).

The 4 patients with normal metabolizer phenotype had normal evolution, without complications during the follow-up period.

CONCLUSIONS

Although done on a relatively small group of patients, the study allowed a clear positive correlation between Clopidogrel rapid metabolizer phenotype and frequency of nonfatal hemorrhagic events. Hemorrhagic events which appeared during the Clopidogrel therapy are not important, but can manifest differently, in different areas (skin, oral mucosa, digestive tract, urinary) and disappear when therapy is stopped. The rapid metabolizer phenotype doesn't offer total protection against repetition of ischemic episodes. Moreover, all the patients with slow metabolizer phenotype had recurrent angina pain and needed emergency interventional cardiology services. Patients with unpredictable phenotype may have unpredictable evolution, some without angina events, some with recurrence and aggravation of the angina, evolution that certainly involves other factors.

INFECTIVE ENDOCARDITIS IN NON-HIV IMMUNOSUPPRESSED PATIENTS (Abstract): Infective endocarditis is a septic illness with sudden or insidious onset that causes heart lesions or aggravates the preexisting ones; during its course it can affect other organs, mortality being high. **Aim:** To identify non-HIV immunosuppressed patients with infective endocarditis, namely those with associated diabetes, hepatitis, cancer, or old age with multiple comorbidities, and to assess the nosocomial risk by Carmeli score. **Material and Methods:** This is a retrospective study using epidemiological, clinical, laboratory and treatment data from 56 patients admitted to and diagnosed with infective endocarditis at the Iasi Infectious Diseases Hospital in the interval January 2008 - May 2012. To these patients we looked for non-HIV immunosuppressed character, having in their pathology association diabetes, chronic hepatitis, malignancy, or other comorbidities. **Results:** From the infective endocarditis patients, 92.8% were found non-HIV immunosuppressed, 25% of them presenting renal failure, and 21.1% having diabetes. The most common Carmeli score obtained was score 2 in 57.1% of the cases. In these patients, the most frequent etiologic agent of infective endocarditis was *Enterococcus faecalis* (16%), followed by *Staphylococcus aureus* (10.7%). **Conclusions:** It was noted that in addition to endocardial damage due to the multiple etiologic agents involved, non-HIV immunosuppression in these patients plays an important role. The association of Carmeli score in patients diagnosed with infective endocarditis is significant, especially in case of adequate therapy initiation for a right treatment of this pathology. **Key words:** INFECTIVE ENDOCARDITIS, DUKE CRITERIA, CARMELI SCORE, NON HIV IMMUNOSUPPRESSION

Sepsis, a life-threatening medical condition, is characterized by whole-body inflammatory state (the so-called systemic inflammatory response syndrome or SIRS) and the presence of a known or suspected source of infection (1, 2). Worldwide, sepsis affects 18 million people every year. In the USA, organ dysfunction occurs in 300/100,000 inhabitants, and mortality from severe sepsis reaches 28%, in other words more than 500 patients die daily from severe sepsis. Recent studies have shown that in Europe the incidence of sepsis in intensive care units is 25% of admitted patients to which other 13% cases of nosocomial infections add up despite the progress made lately

in critical patient care (3).

Cardiac involvement in sepsis is especially due to the circulatory changes induced by chemical mediators and myocardial depressant factors, but also directly by the location of infection at this level: endocarditis, myocarditis, pericarditis, pancarditis (3).

Infective endocarditis (IE) is a septic illness with sudden or insidious onset that causes heart lesions or aggravates the preexisting ones, and which during its course can affect other organs (4). This particular form of systemic infection with unlimited course, in which the primary focus of germs multiplication is the endocardium, still has a great impact in the adult population and not only (5).

In the past 50 years major changes in infective endocarditis have occurred. Thus, there is a significant decrease in mortality, the etiologic spectrum has changed, new antibiotics and new laboratory techniques are now available, echocardiography has improved, and the susceptible population has changed the proportion of persons that are immunocompromised, have prosthetic valves or pacemakers increasing to the detriment of those with rheumatic valvular disease.

The incidence of infective endocarditis remains high, 1.7-6.2/ 100,000 persons / year in the U.S. and Europe, and the yearly mortality is of about 40% (6).

There is a wide diversity of involved etiological agents, these varying depending on valve type (native or prosthetic) and infection type (nosocomial or community acquired). Most infective endocarditis (> 80%) are determined by: *Streptococcus viridans* (30-40%), *Enterococcus species* (5-18%), *Staphylococcus speciae* (*Staphylococcus aureus*, *Staphylococcus epidermidis*: 10-27%), *Escherichia coli* (1.5 to 13%), *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, and Gram-negative bacteria of the HACEK group, responsible for 1-4% of endocarditis (3).

In the studies carried out during the last 4 decades, the risk factors for infective endocarditis were mainly represented by valvular degenerative injuries and heart surgery resulting or not in valve prosthesis, but, over time, with the advent of intravenous drugs, intravascular prostheses, nosocomial exposure, hemodialysis, and age-related valve sclerosis, more common than cardiac rheumatic diseases especially in developed countries, these underwent some changes (7).

Given the recent major changes in infective endocarditis epidemiology and bacteriological profile with strains resistant to various antibiotics, the use of Carmeli score, especially in immunodepressed patients or in those with multiple severe comorbidities became a must (8, 9).

Carmeli score, used to choose the appropriate antibiotic therapy, introduces a new term – health care associated infection, in addition to the two classic types: community acquired and nosocomial. It includes three parameters: contact with the health system, previous antibiotic treatment, and patient characteristics, the highest numeric value representing the value of the score (10).

MATERIAL AND METHODS

We conducted a retrospective study using epidemiological, clinical, laboratory and treatment data from 56 patients admitted to and diagnosed with infective endocarditis at the Iasi Infectious Diseases Hospital in the interval January 1, 2008 - May 31, 2012. Given the association in these

patients of diabetes, malignancy, or other severe comorbidities, we investigated them for non-HIV immunosuppression.

The diagnosis of endocarditis was established based on clinical picture, laboratory data, and Durack/Duke diagnostic and classification criteria (presence of positive blood cultures and echocardiographic appearance of valvular involvement – vegetations as major criteria, and minor criteria).

The non- HIV immunosuppresssed patients, namely those who besides infective endocarditis presented diabetes, chronic hepatitis, neoplasm, and old age, were subsequently identified.

In all these patients, Carmeli score was used to assess the nosocomial risk, according to the following algorithm:

Nosocomial risk assessment (Carmeli score)

A. Degree of contact between patient and the health care system:

1. without contact

2. contact (admissions, nursing home resident) without invasive procedures

3. admissions / prolonged contact with invasive procedures

B. Antibiotic treatment:

1. without antibiotic treatment

2. recent antibiotic therapy

C. Patient characteristics:

1. young without comorbidities

2. elderly + / - multiple comorbidities

3. immunosuppressed AIDS, COPD, malignancies, other causes of immune-depression.

RESULTS AND DISCUSSION

In the interval January 1, 2008 - May 31, 2012, at the Iasi Infectious Diseases Hospital 56 patients with infective endocarditis diagnosed according to the above mentioned criteria were admitted and treated. The yearly distribution of infective endocarditis cases during the study interval was as follows: most cases were recorded in 2010 (19 cases), 11 cases each in 2008 and 2009, 10 cases in 2010, and by May 2012 5 confirmed cases.

The patients were adults aged between 22 and 82 years, mean age 50 years, with most cases belonging to the age group 40-66 years (39 cases). Patients were predominantly males (44 cases), and from urban areas (31 cases).

A positive diagnosis of infective endocarditis was made according to Durack-Duke criteria. The patients presented specific signs and symptoms for infective endocarditis, in line with the inflammatory syndrome detected by laboratory investigations: presence of neutrophilic leukocytosis in the blood count, ESR, fibrinogen, elevated C reactive protein in 58% of cases. Also, a febrile syndrome was present in almost all cases (93%).

Blood cultures were positive in 46.4% of cases. The identified etiologic agents were: *Enterococcus spp., Staphylococcus spp., Streptococcus spp., E. coli, Klebsiella spp. Achromobacter spp.* In 53.6% of cases, blood cultures remained negative (tab. I).

The second major criterion for establishing a diagnosis of certainty of infective endocarditis was transthoracic/transoesophageal echocardiography the target of which is the identification, characterization, and localization of valvular vegetations, the pathologic hallmark of endocarditis. Thus, vegetations of different size and appearance, located on different valves were detected in 96.4% of cases. In only 3.5% of the cases the appearance was normal (tab. II).

The next step was to identify non-HIV immunosuppression in the patients diag-

nosed with infective endocarditis and presenting multiple associated comorbities. Thus, of a total of 56 patients diagnosed with infective endocarditis, 52 patients (92.8%) were found non-HIV immune-depressed (tab. III).

TABLE I

Distribution of positive blood cultures with identified etiologic agents and negative blood cultures

Blood cultures	Cases	
	Number	Percentage
Positive blood cultures	**26**	**46,4**
Enterococcus faecalis	9	16
Staphylococcus aureus	6	10.7
Streptococcus spp.	5	8.9
Escherichia coli	3	5.3
Klebsiella ozaenae	2	3.5
Achromobacter specialis	1	1.7
Negative blood cultures	**30**	**53,6**

TABLE II

Echocardiographic distribution of vegetations

ECHOCARDIOGRAPHIC LOCATION OF VEGETATIONS	**Cases**	
	Number	**Percentage**
Valvular location	**54**	**96,4**
Mitral valve	20	35.7
Aortic valve	13	23.2
Aortic and mitral valve	11	19.6
Tricuspid valve	3	5.3
Pulmonary valve	3	5.3
Location of mitral valve prosthesis	2	3.5
Location on pacemaker electrodes	2	3.5
Normal appearance	**2**	**3.5**

TABLE III

Distribution of non-HIV immunosupression cases

NON-HIV IMMUNOSUPRESSION IN IE PATIENTS	**Cases**	
	Number	**Percentage**
Acute/chronic renal failure	13	25
Insulin-dependent diabetes mellitus	11	21.1
Active chronic hepatitis B +D, C	10	19.2
Chronic heart insufficiency NYHA classified	10	19.2
COPD	5	9.6
Neoplasms	3	5.7

The nosocomial risk was assessed by using Carmeli score. Following this scoring system we found 1 (1.7%) infective endocarditis score 1 (community acquired), 32 (57.1%) score 2 (associated to health care or community acquired but with increased prediction of multidrug resistance), and 23 (41%) score 3 (usually nosocomial), (tab. IV).

The number of hospital stay days in patients with Carmeli score 2 and 3 ranged between 14 and 44 days, they requiring a long-term and targeted antibiogram-guided therapy after culture positivation.

TABLE IV

Nosocomial risk assessment – Carmeli score – in patients with infective endocarditis and non-HIV immunosuppression

Carmeli score	Cases	
	Number	Percentage
SCORE 1	1	1.7
SCORE 2	32	57.1
SCORE 3	23	41

CONCLUSIONS

It was noted that in addition to endocardial damage due to the multiple etiologic agents involved, non-HIV immunosuppression in these patients is an important presence. The association of Carmeli score in patients diagnosed with infective endocarditis is significant with respect to antibiotic resistance; especially when adequate therapy aimed at correctly treating this disease is initiated. Clinical impairment and the need for surgical treatment in some cases require a good knowledge of infective endocarditis assessment, both in terms of associated comorbidities and nosocomial risk.

SEROUS AND MUCINOUS EPITHELIAL OVARIAN TUMORS – A CLINICOPATHOLOGIC STUDY OF 116 CASES (Abstract). Surface epithelial tumors are the most important group of neoplasm of the ovary. These tumors are classified according to the following parameters: cell type, pattern of growth, amount of fibrous stroma, atypia and invasiveness. **Aim**: This study aimed to identify ovarian tumours, especially *borderline* type, by applying last parameters of criteria for histologic diagnostic of ovarian neoplasms. **Material and methods:** The retrospective study included 116 patients with ovarian tumors diagnosed, investigated, surgically treated at the Obstetrical and Gynecological Hospital Botoşani in the past 9 years (2002 - 2010). In this interval were recorded 116 cases of epithelial ovarian tumors. In sample processing, we used formalin for fixation, paraffin for specimen embedding and hematoxilin-eosin for staining. The age of the patients ranged between 19-86 years. **Results:** From 116 cases, 57 (49,1%) were benign, 40 (34,5%) malignant and 19 (16,4%) *borderline*. In our study of benign neoplasms, we included 37 cases of serous tumours (64,9%) and 20 cases of mucinous types (35%). In the group of *borderline* tumours, the serous type was the most frequent (13 cases), followed by mucinous types (6), including 5 cases of intestinal type and 1 of endocervical pattern. The malignant tumors, according with decreasing order of frequency, were the following: 19 serous (47,5%), 8 mucinous (20%), 11 endometroid type (27,5%) and one of each cases of clear cell and small cell tumors (2,5%). **Conclusions:** Of great interest in our research was to identify ovarian *borderline* tumours, still representing a controversial group, in the same time corresponding with a scientiphic progress. Because the spectrum of epithelial tumors is very large, extensive sampling is essential to carry out all these important determinations, because benign, *borderline* and malignant patterns can be found in the same tumor. **Key words**: SEROUS TUMORS, MUCINOUS TUMORS, BORDERLINE PATTERNS

Tumorile epiteliale reprezintă 90% dintre neoplaziile ovariene. Majoritatea se dezvoltă din celulele epiteliului de înveliş, chisturile de incluzie şi, rareori, din focare de endometrioză. Tumorile epiteliale sunt clasificate în funcție de tipul celular, tabloul arhitectural, cantitatea de stromă, gradul de atipie şi caracterul invaziv. Cele mai frecvente sunt de tip seros (46%), urmate de cele de tip mucinos (36%), endometroi-

de (8%), cu celule clare (3%), tranziționale (2%), nediferențiate (2%), mixte (3%) (1,2). Din punct de vedere al caracterului invaziv, tumorile ovariene se clasifică în benigne, *borderline* şi maligne.

Tumorile *borderline* constituie o entitate controversată în patologia neoplazică ovariană. Histologic, acestea prezintă unele caractere de malignitate (atipie celulară moderată, stratificare epitelială, activitate mitotică redusă) dar nu prezintă invazie stromală. Evoluția clinică a acestor tumori este cel mai adesea benignă, excepție făcând cele care prezintă implanturi peritoneale invazive care pot evolua similar tumorilor maligne (2).

Scopul acestui studiu îl reprezintă aprecierea valorii criteriilor histopatologice pentru diagnosticul tumorilor ovariene în colorație uzuală hematoxilină-eozină şi evidențierea caracteristicilor histopatologice ale tumorilor *borderline* în tabloul neoplazic ovarian.

MATERIAL ŞI METODE

Studiul retrospectiv a fost efectuat pe un lot de 116 cazuri de tumori ovariene epiteliale investigate şi operate la Spitalul de Obstetrică şi Ginecologie Botoşani între anii 2003-2010. Vârsta pacientelor a fost cuprinsă între 19 şi 86 ani.

Am efectuat o prelevare extensivă a fragmentelor tumorale, în special din ariile adiacente epiteliului superficial, ariile solide, formațiunile papilare şi baza acestora. Numărul de blocuri prelevate din fiecare tumoră a variat în funcție de dimensiunea tumorii şi aspectul macroscopic, în total au fost 843 blocuri.

Pentru diagnosticul anatomo-patologic am folosit tehnica uzuală: fixarea în formaldehidă 10%, includerea în parafină, secționarea la 5 microni şi colorația hematoxilină-eozină.

REZULTATE

1. Distribuția pe categorii de tumori

Din cele 116 cazuri investigate, 57 au fost cu tumori benigne (49,1%), 40 maligne (34,5%) şi 19 tumori ovariene *borderline* (16,4%). În cazul tumorilor epiteliale benigne, 64,9% au fost seroase şi 35% mucinoase. 19 dintre tumorile maligne identificate de noi au fost seroase (47,5%), 8 mucinoase (20%), 11 endometroide (27,5%), una cu celule clare (2,5%) şi 1 caz de carcinom cu celule mici (2,5%).

2. Tumorile seroase ovariene (69 de cazuri) au avut următoarea reprezentare: 37 (53,7%) benigne, 13 (18,9%) *borderline*, şi 19 (27,4%) maligne. 18,1% dintre tumorile seroase au avut afectare bilaterală.

Tumorile seroase benigne au prezentat aspecte microscopice variate: chisturi delimitate de epiteliu de tip tubar, unistratificat (chistadenom), stromă fibroasă (chistadenofibroame), atipie nucleară minimă sau absentă, mitoze rare. Rar, epiteliul a prezentat papile neramificate (chistadenom papilar).

Tumorile seroase borderline, identificate de noi în 13 cazuri, au fost în 92,3% din cazuri unilaterale şi în 7,3% din cazuri cu localizare bilaterală. La aceste paciente nu s-au evidențiat implanturi peritoneale.

Criteriile de diagnostic aplicate de noi tumorilor seroase *borderline* au fost: hiperplazie epitelială sub formă de pluristratificare, micropapile, aspecte cribriforme sau grupuri de celule, atipie uşoară sau moderată, cuiburi de celule detaşate intrachistic, activitate mitotică variabilă, de obicei minimă, prezență de corpi psamomatoşi. Proliferarea celulară variază de la celule mici, uniforme, cu nuclei hipercromatici, la celule mari, cu citoplama eozinofilă.

În cazul tumorilor *borderline* investigate de noi am indentificat următoarele aspecte histopatologice: absența invaziei stromale la toate cazurile, hiperplazie epitelială cu proliferare papilară cu aspect ramificat (92,3% dintre cazuri), proliferare glandulară (46,1%), cuiburi sau celule izolate detaşate (92,3%) (fig.1), celule detaşate intrachistic cu citoplasma eozinofilă şi nucleul hipercromatic (61,5%). Constant, am găsit atipie celulară uşoară sau moderată (fig. 2) şi un număr mic de mitoze. Un singur caz (7,6%) a prezentat aspect de proliferare epitelială cu arhitectură cribriformă. Am identificat corpi psamomatoşi în 15,4% dintre tumorile *borderline*. În 23% dintre cazuri, aspectele *borderline* au apărut pe arii mici, coexistând cu aspecte benigne.

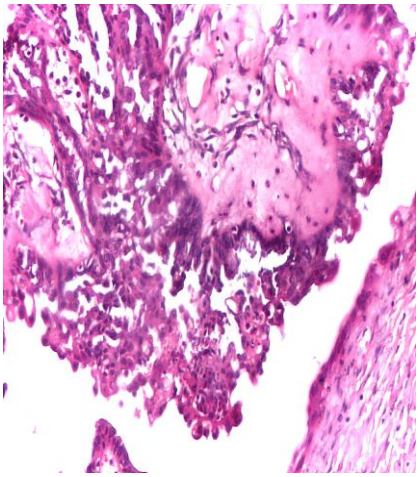

Fig. 1. Tumora seroasa *borderline* cuiburi celulare detaşate (HEx10)

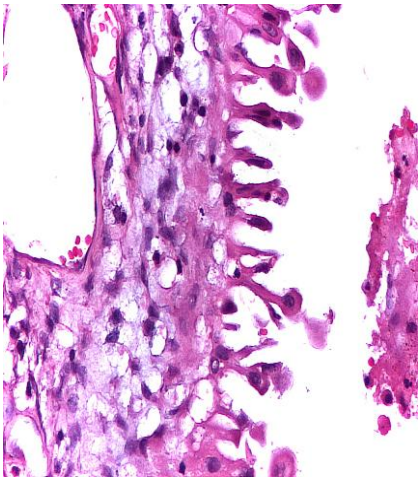

Fig. 2. Celule cu citoplasma eozinofilă, atipie nucleară moderată (HEx20)

Tumorile seroase maligne, în număr de 19, au fost reprezentate de chist-adenocarcinoame seroase slab diferențiate (63,2%) şi bine diferențiate (36,8%), distincție realizată în funcție de aspectul arhitectural, atipia citologică şi numărul de mitoze. Microscopic, modul de creştere al acestor tumori a fost sub formă de glande, papile cu arhitectură complexă, proliferare epitelială solidă cu prezență de spații sub formă de fantă. Au fost prezente atipiile celulare, şi caracterul invaziv. 26% dintre aceste tumori au prezentat corpi psamomatoşi.

3. Tumorile mucinoase identificate de noi au inclus cazuri benigne (58,8%), *borderline* (17,6%), maligne (23,6%).

Tumorile benigne au fost reprezentate de 18 chistadenoame mucinoase de tip intestinal, cu prezență de celule caliciforme, 2 cazuri de chistadenoame mucinoase de tip endocervical cu celule cilindrice, nuclei bazali şi o cantitate crescută de mucină intracitoplasmatică. Aceste tumori au prezentat o stratificare minimă sau absentă şi atipie celulară redusă sau absentă.

Cele 6 cazuri de *tumori borderline mucinoase* au fost diagnosticate ca fiind 5 de tip intestinal, unilateral, şi un caz de tip endocervical, unilateral. Tumorile *borderline* mucinoase de tip intestinal au prezentat papile filiforme intrachistice, unele cu aspect coalescent la nivelul extremității

distale, epiteliu de tip intestinal, cu prezență de celule caliciforme, stratificare celulară redusă la 2-3 straturi, atipie redusă, mitoze rare. Epiteliu cu aspect benign a coexistat la nivelul tumorilor polichistice. Tumora *borderline* mucinoasă de tip endocervical a prezentat proliferări papilare intrachistice acoperite de epiteliu mucosecretor de tip endocervical cu atipie moderată, celule detaşate intrachistice, infiltrat inflamator cu polimorfonucleare şi mitoze rare.

Tumorile maligne mucinoase au fost reprezentate de chistadeno-carcinoame mucinoase de tip intestinal. Microscopic, aceste tumori au prezentat proliferări glandulare cu arhitectură cribriformă sau cu aspect labirintic, glande cu contur neregulat cu caracter invaziv expansiv, proliferări celulare cu mai mult de 4 straturi, pierderea aspectului mucosecretor, atipie citonucleară. În 4 cazuri (50%) au fost identificate şi arii cu aspect *borderline*.

DISCUȚII

Tumorile epiteliale reprezintă cea mai mare parte dintre neoplaziile ovariene. Acestea se dezvoltă din epiteliul de înveliş al ovarului dar mai ales din epiteliul invaginat ce formează chisturile de incluzie (1,2). Într-un număr mai redus de cazuri, aceste tumori se pot dezvolta din focare de endometrioză: tumori endometroide (3) şi posibil cele mucinoase (2).

După OMS (1), tumorile epiteliale ovariene se clasifică în funcție de tipul celular (seros, mucinos, endometroid, celule clare, tranzitional), tabloul macroscopic (chistic, solid, mixt), proporția stromei fibroase, prezența atipiei, şi după caracterul invaziv.

Nucci et al. (2) recomandă, în cazul ovarului cu aspect macroscopic tumoral, prelevarea unui bloc pentru fiecare 1-2 cm din diametrul maxim al tumorii. Noi considerăm că pentru un diagnostic corect este necesară recoltarea multiplă, în special din ariile solide, ariile adiacente epiteliului de înveliş, formațiunile papilare şi baza acestora.

Tumorile seroase au prezentat în studiul nostru un procent de 59,4%, în timp ce în studiul efectuat de Nucci, acestea reprezintă aproximativ 50% din neoplaziile epiteliale.

Pe lotul analizat de noi, tumorile benigne au reprezentat 53,7% dintre neoplaziile seroase, procent apropiat de cel menționat de Rosai (50%) (3).

După clasificarea OMS, tumorile seroase *borderline* reprezintă aproximativ 15% din tumorile seroase. Acestea apar la vârste cu 10-15 ani mai mici decât în cazul adenocarcinoamelor, respectiv 45 ani versus 60 de ani (2).

În studiul nostru, proporția cazurilor *borderline* în cadrul neoplaziilor seroase a fost de 18,9%. Vârsta pacientelor a fost între 19-70 de ani, cu o medie de vârstă de 44,5 ani.

În literatură (4,5) au fost descrise alte trei variante rare (5-10%) de tumorii seroase *borderline*: varianta micropapilară, cea cu microinvazie, şi respectiv cea cu prezența carcinomului intraepitelial. În forma micropapilară au fost observate papile lungi şi subțiri, aspecte de tip cribriform pe o lungime de 5 mm (1,2), micropapilele fiind acoperite de celule cubice sau rotunde, cu raport nucleu/citoplasmă mărit (6,7). Criteriile microscopice pentru microinvazie au fost: celule citoplasma eozinofilă izolate sau în grupuri mici, neregulate, prezente în stroma fibroasă (8,9), de obicei înconjurate de mici spații libere. Proliferarea epitelială nu trebuie să depăşească 10 mm^2. Am identificat în studiul nostru un singur caz (7,6%) de microinvazie dezvoltat pe o tu-

moră *borderline* seroasă, ceea ce confirmă raritatea acestor leziuni.

Criteriile prognostice cunoscute în cazul tumorilor *borderline* sunt reprezentate de prezența implantelor peritoneale invazive, stadiul clinic şi aspectul histopatologic. Evoluția acestor tumori rămâne neschimbată chiar dacă există focare de microinvazie. Conform aprecierilor lui Rosai (3), prognosticul acestor tumori este mai favorabil (asemănător celor benigne) atunci când aspectele *borderline* apar doar focal într-o tumoră cu aspect benign (chistadenoame cu arii focale proliferative).

În lotul analizat, proporția carcinoamelor seroase (27,4%) a fost apropiată de valorile de referință (35%) (3) din cadrul tumorilor seroase. Ele au prezentat însă un procentaj mai mic (47,5%) comparativ cu alte studii (2, 5), în care ele au reprezentat 75% din cadrul neoplaziilor epiteliale maligne. Acest fapt se datorează faptului că noi am identificat în studiul nostru un număr crescut de tumori endometroide maligne. Aplicând criteriile de malignitate recomandate de OMS (1) şi Silverberg (4) la cazurile studiate de noi, a rezultat că 65% din tumorile maligne seroase au fost de grad înalt, iar 35% au prezentat un grad redus de malignitate.

Tumorile mucinoase, conform recomandărilor OMS (1), se împart din punct de vedere histologic în 2 categorii: tip intestinal şi tip endocervical.

În studiile efectuate de Rosai, tumorile benigne au fost cele mai frecvente neoplazii mucinoase ale ovarului (80%), dar pe lotul examinat de noi, frecvența tumorilor mucinoase benigne a fost mai redusă, în favoarea cazurilor maligne şi *borderline* (58,8%). Cele mai numeroase tumori benigne au fost cele de tip intestinal (90%), în timp ce doar 10% au fost de tip endocervical.

Noi am identificat tumorile *borderline* în procent de 17,6%, similar altor studii (15%) (3, 7). Cele mai frecvente au fost cele de tip intestinal (83%) urmate de tipul endocervical (17%). Toate cazurile de tumori *borderline* intestinale au prezentat şi arii cu aspect benign.

Tumorile mucinoase maligne au reprezentat în studiul nostru 23,5% din cazuri, comparativ cu Nucci et al. (2) unde procentul acestora a fost semnificativ mai mic (5%). Toate carcinoamele mucinoase au fost de tip intestinal iar în 50% din cazuri au fost prezente şi aspecte de carcinom *in situ* sau *borderline*. Carcinomul intraepitelial a prezentat aspecte focale de stratificare celulară intraepitelială cu arhitectură papilară, cribriformă sau solidă, atipie severă şi mitoze frecvente.

CONCLUZII

Tumorile ovariene epiteliale reprezintă o temă de actualitate prin incidența crescută a cazurilor raportate. Studiul nostru a identificat un spectru larg de tumori ovariene epiteliale, atât din punct de vedere al epiteliului proliferat, cât şi al gradului de proliferare celulară şi de atipie citonucleară.

Cele mai frecvente neoplazii epiteliale au fost de origine seroasă. Tumorile *borderline* au reprezentat 16,4% din cazuri şi au fost identificate la paciente cu o medie de vârsta de 44,5 ani.

Cercetările noastre au evidențiat faptul că pentru diagnosticul corect al tumorilor ovariene este necesară prelevarea de numeroase fragmente în cazul formațiunilor intrachistice şi în cazul tumorilor polichistice, pentru că pot coexista, în aceeaşi tumoră, aspecte benigne, *borderline*, microinvazie şi aspecte maligne.

NOUTĂȚI

CHIRURGIA BARIATRICĂ VERSUS TRATAMENTUL MEDICAMENTOS INTENSIV LA PACIENȚII OBEZI CU DIABET ZAHARAT

Cercetarea continuă studiile observaționale care evidențiaseră ameliorarea controlului diabetului după realizarea chirurgiei bariatrice. Acest studiu randomizat a comparat eficacitatea terapiei medicamentoase față de terapia medicamentoasă în asociere cu procedurile de chirurgie bariatrică, înrolând 150 pacienți obezi, cu diabet tip 2 necontrolat. Vârsta medie a pacienților a fost de 49±8 ani, 66% fiind femei. La intrarea în studiu hemoglobina glicozilată avea valoarea medie de 9,2±1,5%, principalul obiectiv propus fiind scăderea acesteia la valoarea de 6% după 12 luni de tratament. 93% dintre pacienți au fost urmăriți până la finalizarea studiului. Obiectivul primar a fost realizat la 12% dintre pacienții aflați sub tratament medicamentos și la peste 35% dintre pacienții cu terapie de asociere chirurgicală și medicamentoasă (p=0,002). Controlul glicemic s-a ameliorat până la 7,5±1,8% în grupul cu terapie medicamentoasă, 6,4±0,9% în grupul cu by-pass gastric și 6,6±1,1% în grupul cu gastrectomie. Scăderea în greutate a fost mult mai semnificativă la pacienții care au beneficiat de chirurgie (p<0,001). Consumul de medicamente hipoglicemiante și hipolipemiante a scăzut semnificativ la pacienții care au beneficiat de intervenții chirurgicale și au crescut în celălalt lot. Indexul de insulinorezistență HOMA-IR s-a îmbunătățit semnificativ după chirurgie. Aceste rezultate sunt în favoarea tratamentului chirurgical dar trebuie confirmate pe termen lung. (Schauer PR, Kashyap SR et al. Bariatric surgery versus intensive medical therapy in obese patients with diabetes, *N Engl J Med* 2012; 366: 1567-1576)

Spitalul Clinic de Recuperare - Iaşi,
2. Clinica de Reumatologie

DESCRIPTIVE CLINICAL STUDY ON A SAMPLE OF PATIENTS WITH GONARTHROSIS, ASSISTED IN THE HOSPITAL OF REHABILITATION IASI (Abstract)**: The aim** of our descriptive study was to assess a sample of patients with knee osteoarthritis. **Material and methods**: A sample of 295 patients was assessed regarding demographical features, co morbidities, some laboratory investigations and therapeutically interventions. **Results**: The predominance of females (81.4%), urban area (51.8%), age group over 50 (90.2%), primary bilateral disease (90.1%), associated with hip osteoarthritis. coxarthrosis (13.9%), essential arterial hypertension (10.9%), osteoporosis (9.5%) or obesity (8.1%) were the most frequent features of a patient admitted for knee osteoarthritis. Among therapeutically methods, patients received ultrasounds in 61.1% of cases, and kinetotherapy in 16.6%. **Conclusions**: Our study presented news aspects regarding knee osteoarthritis, in a geographical area of north-east of Romania. **Key words**: GONARTHROSIS, PREVALENCE, PHYSICAL THERAPY.

Gonartroza este o formă frecventă a reumatismului degenerativ cu localizare la nivelul articulației genunchiului, afecțiunea fiind supărătoare şi frecvent invalidantă. Boala este o problemă majoră de sănătate publică, la nivel mondial, precum şi în România, prin frecvența mare la populația de peste 40 de ani, afectând 25-30% din persoanele în vârstă de 45-64 de ani şi peste 60% dintre cele peste 65 de ani (1, 2). Etiologic, gonartroza poate fi primitivă şi secundară. Gonartroza primitivă este mai frecventă la femeie; apare la vârsta de 40-70 de ani. Gonartroza secundară poate fi urmarea unor tulburări ale biomecanicii articulare de origine traumatică, de origine statică sau a unor boli localizate la nivelul genunchiului (3, 4). Tratamentul deosebit de complex şi desfăşurat pe perioade lungi de timp are ca scop combaterea durerii, a inflamației supraadăugate, diminuarea impotenței funcționale, menținerea funcției articulare, micşorarea handicapului şi, în general, ameliorarea calității vieții (1, 3, 4, 5).

MATERIAL ŞI METODE

Studiul clinic de tip descriptiv a fost efectuat pe un lot de 295 pacienți diagnosticați cu gonartroză în variate stadii de evoluție şi care au fost internați şi asistați terapeutic şi evolutiv în Spitalul Clinic de Recuperare Iaşi, în perioada 1 ianuarie – 31

decembrie 2010. Acest lot a cuprins şi reinternările, deci, studiul se referă la prevalența bolii.

Culegerea informațiilor s-a realizat prin evaluarea foilor de observație ale pacienților, precum şi a raportărilor statistice ale Spitalului Clinic de Recuperare, Iaşi. Criteriul de includere în lotul studiat s-a referit la codurile OMS pentru gonartroze ca diagnostic principal de externare, şi anume: M17.0 Gonartroză primara, bilaterală; M17.1 Alte gonartroze primare; M17.4 Alte gonartroze secundare, bilaterale; M17.5 Alte gonartroze secundare.

Pentru prelucrarea şi interpretarea datelor acumulate am utilizat programele computerizate *MS Excel*, *EpiInfo*, iar metodele biostatistice au inclus calcularea prevalenței globale, specifice, a probabilității, regresiei liniare şi tendinței.

REZULTATE ŞI DISCUȚII

1. Structura lotului studiat. Repartiția pe sexe a evidențiat predominanța femeilor (81,4%), cu un raport masculin / feminin de 0,23. Această valoare obținută de noi este în concordanță cu rezultatele altor studii privind predominanța gonartrozei la sexul feminin, cu o diferență semnificativă statistic ($p < 0,001$) (tab. I).

TABELUL I

Repartiția pe sex şi categorii de diagnostic

Diagnosticul - Coduri OMS	Sex feminin	Sex masculin	Total
Gonartroză primara, bilaterală - M17.0	220	46	266
Alte gonartroze primare - M17.1	8	4	12
Alte gonartroze secundare, bilaterale - M17.4	11	4	15
Alte gonartroze secundare - M17.5	1	1	2
Total	**240**	**55**	**295**

Repartiția pe medii de reşedință a pacienților cu gonartroză a fost în favoarea celui urban (51,8%), însă cu diferențe statistic nesemnificative, în toți anii luați în studiu ($p > 0,05$). Această constatare se regăseşte în datele din literatura de specialitate (2, 3, 4, 5), publicate în străinătate, cât şi în România (tab. II).

TABELUL II

Repartiția pe medii de reşedință şi categorii de diagnostic

Diagnosticul - Coduri OMS	Mediul urban	Mediul rural	Total
Gonartroză primara, bilaterală - M17.0	139	127	266
Alte gonartroze primare – M17.1	8	4	12
Alte gonartroze secundare, bilaterale - M17.4	4	11	15
Alte gonartroze secundare - M17.5	2		2
Total	**153**	**142**	**295**

Repartiția pe grupe de vârstă. Gonartroza a fost înregistrată la grupele de vârstă mare şi s-a remarcat faptul că, odată cu înaintarea în vârstă, creşte brusc şi incidența acestei patologii, mai ales după 50 ani, prin cumularea diferiților factori de risc implicați în etiopatogenia bolii. Calcularea regresiei liniare arată faptul că prevalența

cazurilor de gonartroză are o tendinţă crescătoare spre grupele de vârstă de peste 50 ani (90,1%). Date similare au fost menţionate şi în alte cercetări (2, 5), de unde rezultă necesitatea preocupării pentru depistarea precoce a gonartrozei, cu deosebire pentru femei şi grupele de persoane vârstnice (fig. 1).

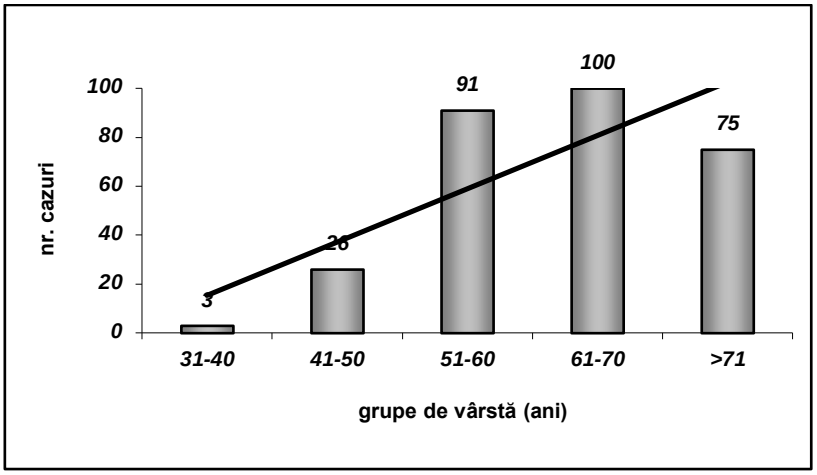

Fig. 1. Repartiţia pe grupe de vârstă a 295 pacienţi cu gonartroză, incluşi în studiul descriptiv

2. Aspecte ale comorbidităţilor la pacienţii din lotul studiat. Din analiza de statistică descriptivă, se constată că prevalenţa specifică a gonartrozei primare, bilaterale, are cea mai mare valoare în lotul studiat (fig. 2). Aceste rezultate nu le putem considera semnificative statistic, însă ele se suprapun peste rezultate asemănătoare ale diferitelor studii de prevalenţă a artrozelor, în variate regiuni geografice (2, 3).

Cele mai importante *patologii asociate* la cazurile cu gonartroză au fost următoarele: hipertensiunea arterială esenţială (HTAE) (10,9%); osteoporoza (9,5%); obezitatea (8,1%); traumatisme locale (gonartroza posttraumatică) (3,7%).

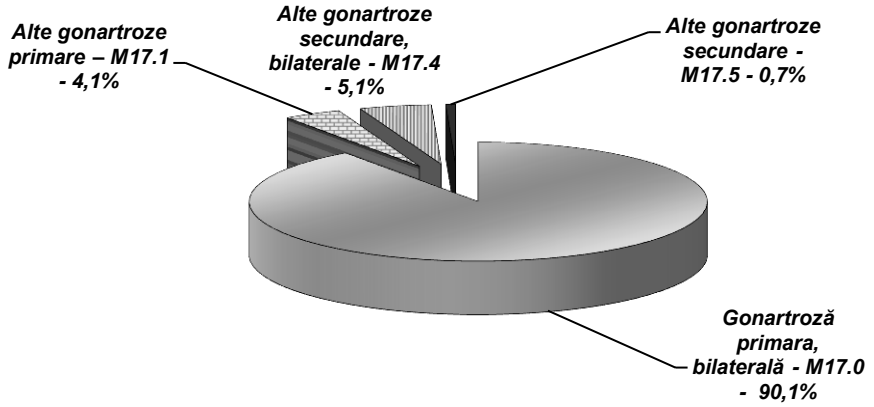

Fig. 2. Distribuţia cazurilor în funcţie de diagnosticul principal de externare

Altă asociere importantă etiologic, medical şi terapeutic, dar şi pentru criteriile de evaluare a calității vieții pacientului, a fost cea dintre gonartroză şi coxartroză (13,9%), fapt menționat şi în lucrări din literatura de specialitate (5, 6) (fig. 3). Datele obținute, referitoare la patologiile asociate gonartrozei, sunt în acord cu cele concluzionate de alți cercetători (2, 4, 5).

Dintre *factorii incriminați în producerea gonartrozei*, cei mai importanți sunt factorii endocrini, boala fiind mai frecventă la femeia după menopauză; obezitatea, deoarece studiile arată că două treimi din bolnavi sunt supraponderali; tulburări venoase, conform cu numeroase studii, mai mult de 35% din bolnavii cu gonartroză au varice la membrele inferioare. Menținerea unei greutăți corporale în limitele normale vârstei, taliei şi sexului pacientului, adoptarea unui regim de viață activ, bogat în exerciții fizice de întreținere a funcționalității articulare şi a tonusului muscular normal; evitarea exercitării unui stres fizic semnificativ si prelungit asupra articulației genunchiului reprezintă câteva din metodele prin care gonartroza poate fi prevenită (2, 3, 4).

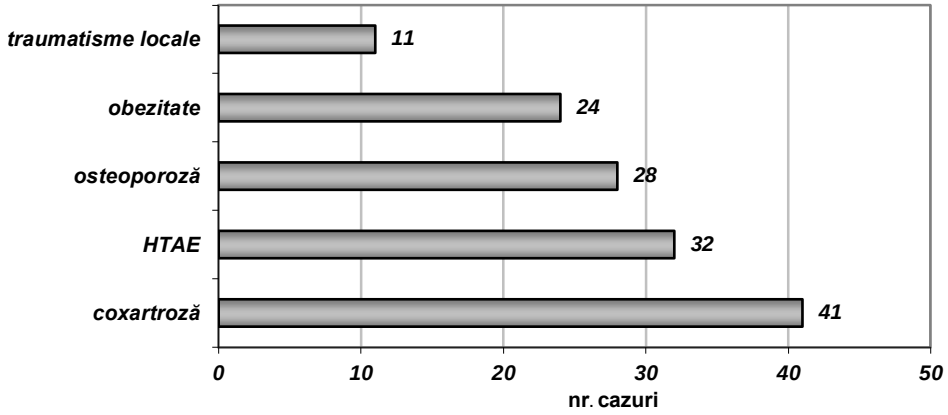

Fig. 3. Distribuția celor mai frecvente comorbidități la pacienții cu gonartroză

3. Investigațiile de laborator de tip biochimic au evidențiat faptul că, din cele 295 probe de sânge pentru glicemie, 19 (6,5%) au avut valori peste 120 mg/dl, din care 3 cazuri bărbați (5,5% din total bărbați) şi 16 cazuri femei (6,7% din total femei). Colesterolemia totală a fost investigată la un sublot de 45 pacienți din lotul total studiat; valori peste 200 mg% au fost observate la 5 cazuri din cei 7 pacienți de sex masculin incluşi în sublot (71,4%) şi la 27 din cele 38 femei (71,1%). Aceste aspecte relevă faptul că pacienții cu gonartroză, luați în studiu, prezintă multiple comorbidități care trebuie luate în considerație pentru alegerea celor mai potrivite metode terapeutice.

4. Unele aspecte privind procedurile terapeutice la bolnavii cu gonartroză. Din lotul de 295 cazuri de gonartroze, am remarcat faptul că la 180 (61,1%) s-a aplicat terapia cu ultrasunete; 173 (58,6%) cea utilizând curenți diadinamici; 150 (53,3%) – TENS, iar kinetoterapie la 49 pacienți (16,6%), dintre care 44 au primit proceduri la nivelul articulației genunchiului şi 21 pacienți la nivelul mușchilor membrelor inferioare (fig. 4).

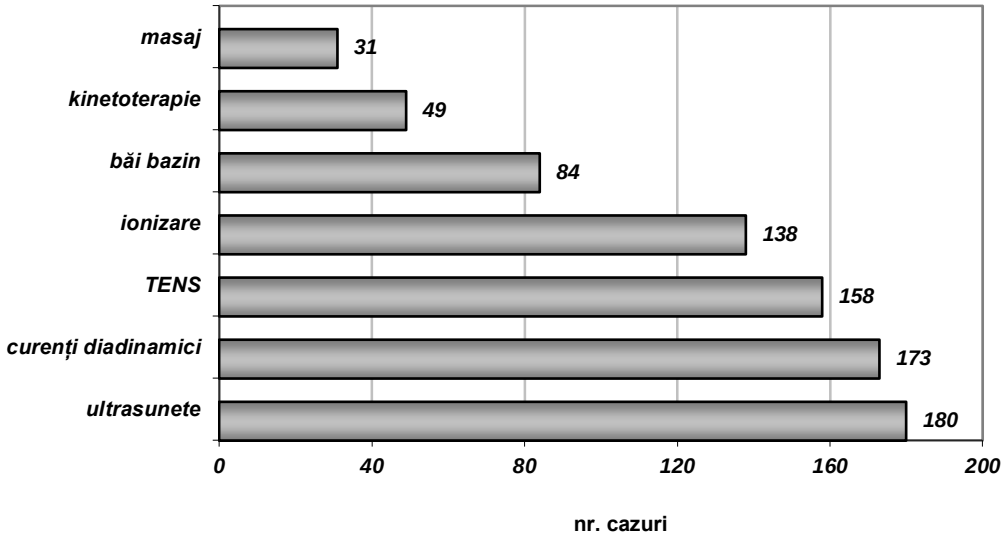

Fig. 4. Distribuția procedurilor fizice aplicate pacienților cu gonartroză primară bilaterală

Exercițiul aerob are indicații în reeducarea genunchiului artrozic. Mersul reprezintă un mijloc eficient pentru genunchiul stabil, urmărindu-se un program gradat, fiecare ședință fiind precedată de exerciții de încălzire, cu mişcări active din toate articulațiile, urmate de *stretching* (7). Mobilizarea articulațiilor învecinate şi tonifierea grupelor musculare ale membrului inferior reprezintă, de asemenea, o prioritate a kinetoterapiei la pacienții cu gonartroză.

Tolerabilitatea terapiei fizice este bună, cu efecte secundare tranzitorii şi uşoare, dar cu beneficii de lungă durată, pentru pacienții cu gonartroză, îmbunătățind semnificativ capacitatea funcțională a articulației şi scăzând simptomatologia dureroasă. Exercițiul fizic poate reprezenta o alternativă utilă la tratamentul farmacologic al gonartrozei, mai ales pentru pacienții care nu tolerează efectele adverse ale medicamentelor (5, 6).

Prognosticul pacienților cu gonartroză depinde foarte mult de evoluția bolii, anterior prezentării la medic şi începerii terapiei. Dacă afecțiunea a evoluat, există riscul ca evoluția să fie influențată de boala de bază, deoarece sunt limitate mişcările în una dintre cel mai importante articulații ale organismului. Din acest motiv, specialiştii recomandă pacienților să se adreseze unui medic, în cazul în care observă modificări locale, la nivelul articulației sau dacă aceasta a devenit dureroasă, iar funcționalitatea ei s-a redus (2, 5).

CONCLUZII

Rezultatele studiului a adus noi informații privind descrierea gonartrozei, utilizând criterii populaționale, dar şi clinice şi terapeutice, care caracterizează populația din nord-estul României. Pacienții incluşi în lotul de studiu au fost urmăriți clinic, imagistic şi evolutiv, pentru a observa, descrie şi analizează impactul metodelor terapeutice utilizate la aceştia asupra răspunsului biochimic şi imunologic. Prin acest studiu, continuat cu rezultatele legate

de corelațiile biostatistice ale răspunsurilor biologice evolutive, vom putea concluziona şi noi dacă variatele proceduri fizice au beneficii asupra gonartrozei, atât imediate, cât şi pe termen îndelungat.

De asemenea, nu trebuie neglijat impactul social, economic, dar şi emoțional familial, al acestei patologii, cu rezultate negative pentru bolnav, familia acestuia, dar şi referitor la costurile economice legate de concediile medicale, pensionări de invaliditate, precum şi scăderea importantă a indicelui de calitate a vieții, odată cu înaintarea în vârstă.

PULMONARY ARTERIAL HYPERTENSION-A CHALLENGE FOR RESPIRATORY REHABILITATION (Abstract): Chronic pulmonary arterial hypertension (PAH) is a severe disease of the pulmonary vasculature, characterized by increased resistance at this level, and increased pulmonary artery pressure, ultimately leading to right heart failure and death. The current therapeutic strategy in PAH includes a stepwise approach, the first step being supportive therapy, supervised rehabilitation program, and psychosocial support, followed by pharmacological treatment according to the vasoreactive or nonreactive type of PAH and prognostic determinants. Small trials have shown that PAH patients experience reduced dyspnea and fatigue, as well as a higher level of physical activity, a greater distance to the 6-minute walk test, and improvement in the quality of life after completing a pulmonary rehabilitation program. Low-level graded endurance and resistance exercises, as well as inspiratory and peripheral muscles training, are recommended, along with careful patients' education regarding their own illness, nutrition, and safe level of physical effort. The optimal type of physical activity, intensity, and duration of training are issues still under debate. **Keywords:** PULMONARY ARTERIAL HYPERTENSION, RESPIRATORY REHABILITATION.

Chronic pulmonary arterial hypertension (PAH) is a severe disease of the pulmonary vasculature, characterized by increased resistance at this level and increased pulmonary artery pressure, ultimately leading to remodeling of the right ventricle, right heart failure, and death (1, 2, 3).

Incidence and prevalence of PAH are difficult to estimate because of the ongoing development of the definition of PAH, current data suggesting the rise of this life-threatening condition. The management of the disease is complex and requires the intervention of a multidisciplinary team including cardiologists, pulmonologists, rheumatologists, physiotherapists, and trained specialists in cardiorespiratory rehabilitation (4, 5).

The main symptoms are fatigue, exertional dyspnea, chest pain, dizziness, and

syncope. The current definition of PAH involves the presence of a mean pulmonary artery pressure ≥ 25 mmHg at rest, as measured by right heart catheterization.

Depending on pathophysiological mechanisms, PAH is classified into five main categories with clinical relevance (1, 6) (tab. I).

TABLE I
Clinical classification of pulmonary artery hypertension
(adapted according to 2015 ESC/ERS Guidelines) (6)

Main Categories	
I.	Pulmonary arterial hypertension
II.	Pulmonary hypertension due to left heart disease
III.	Pulmonary hypertension due to lung diseases and/or hypoxia
IV.	Chronic thromboembolic pulmonary hypertension
V.	Pulmonary hypertension with unclear etiology/multifactorial mechanisms

Therapeutic strategy – current recommendations

The therapeutic strategy in PAH has evolved over the past decades with the deepening of knowledge about this complex condition; the goal is to position and keep the patient in a lower risk class, associated with good exercise capacity, an acceptable function of the right ventricle, a good quality of life, and a low mortality risk. Currently, there is a stepwise approach to the treatment; three main strategies have been described (6, 7):

I. general measures, supportive therapy, patient orientation to centers with PAH expertise and vasoreactivity testing for indication of treatment with calcium channel blockers;

II. high-dose calcium channel blocker therapy (vasoreactive PAH) or other approved drugs for non-vasoreactive PAH, in accordance with the prognostic risk;

III. in case of inappropriate response to stage II treatment, the use of approved drug combinations for PAH and the lung transplant option.

General measures recommended as the first line in the management of patients with PAH involve physical activity and supervised rehabilitation, psychosocial support, patient and family education in the multiple aspects of the disease, increased adherence to treatment (5, 6, 7).

Adaptation to exercise in patients with pulmonary hypertension

The reduced physical activity level of patients with PAH results primarily from the decrease in peripheral and respiratory muscle strength, measured by the maximal inspiratory pressure (MIP) and maximal expiratory pressure (MEP), which are significantly lower in PAH patients compared to healthy subjects of comparable age and gender (8, 9).

Exercise intolerance in patients with PAH is a complex interplay between respiratory, cardiovascular, and musculoskeletal systems, altered hemodynamics of pulmonary circulation being the key element. Increased pulmonary peripheral vascular resistance affects the right ventricle (RV) and

results in a decoupling between these two anatomical elements. Over time, dilated RV compresses left ventricle (LV) and affects its distensibility and systolic flow, increasing pulmonary artery pressure (PAP) contributing in limiting exercise capacity. Another link is the increase in ventilatory demand and alteration of muscle contraction through low peripheral oxygen delivery, because of circulatory changes, resulting in lactic acid accumulation, effort limitation, and hyperactivation of the sympathetic vegetative system in response to cardiac output, like what happens in left heart failure (10).

Adaptation to physical training produces changes in the right ventricle and muscle strength, leading to increased systolic volume and the ejection fraction of RV, as well as reduced flux resistance in the pulmonary artery, simultaneously with pulmonary perfusion improvement, as MRI imaging demonstrated.

Respiratory rehabilitation finds its place in the first step of therapeutic approach, the main components of the training being represented by the respiratory muscles training, aerobic endurance training, and strength exercises, but the results of the studies, although promising, have not yet allowed the development of standardized training protocols (5, 6, 8, 9, 10).

Cardio-pulmonary rehabilitation in PAH has multiple beneficial respiratory, hemodynamic, and muscle effects (tab. II).

TABLE II

Adaptive mechanisms to physical training in pulmonary hypertension

(adapted according to Babu *et al.*, 2017) (10)

Effects on the right ventricle	Hemodynamic effects	Effectson the respiratory system	Muscle effects
Improved RV Function	Improved pulmonary perfusion	Increased forced expiratory volume (FEV_1)	Increased strength of diaphragm and quadriceps muscles
Increased RV stroke volume and ejection fraction	Decreased pulmonary flow resistance	Increased forced vital capacity (FVC)	Increased capillarization and oxidative capacity
	Increased cardiac output Decreased mPAP		

Positioning of the respiratory rehabilitation in the therapeutic strategy of pulmonary hypertension

Traditionally, the physical effort has been longtime contraindicated in patients with pulmonary hypertension because of the potential for an abrupt decrease in cardiac output during exercise and impairment of right ventricular function. Over the past decades, a growing body of evidence has demonstrated the safety and effectiveness of exercise dosing training, with benefits in terms of exercise capacity, peak oxygen consumption, and quality of life, but the findings are still not very extensive and there are many gaps concerning workout

for this category of patients (11).

Small trials have shown that PAH patients experience reduced dyspnea and fatigue, as well as a higher level of physical activity, a greater distance to the 6-minute walk test, and an improvement in the quality of life after completing a pulmonary rehabilitation program (tab. III).

TABLE III

The main effects of cardio-respiratory rehabilitation programs in patients with pulmonary hypertension of various etiologies

Main Effects
Improved exercise capacity (effort tolerance, endurance) (12-15)
Improved quality of life (12, 15, 16)
Decreased pulmonary artery pressure (12)
Improved peak oxygen consumption (17)
Hemodynamic improvement (right ventricular function, pulmonary perfusion) (17, 18)

Initial exercise effort assessment is of major importance, the most commonly used methods being the 6-minute walk test and cardiorespiratory exercise test, which is the gold standard and the most evidence-based in terms of diagnostic recommendations, prognosis, and evaluation of therapeutic efficacy (10).

Evaluation of a patient with PAH before the inclusion in a respiratory rehabilitation program should include several steps, feasible in a rehabilitation center equipped with multiple exploration facilities and access to a multidisciplinary team (19):

- Electrocardiogram, echocardiography – cardiologist;
- Right heart catheterization – interventional cardiologist;
- Diffusion capacity evaluations – pulmonologist/exercise physiologist;
- Pulmonary function tests (spirometry)-pulmonologist/exercise physiologist;
- Cardiopulmonary exercise testing-pulmonologist/ exercise physiologist / cardiologist (20);
- Six-minute walk test – exercise physiologist/physiotherapist/nurse (21);
- Muscle strength assessment (inspiratory and peripheral muscles) – exercise physiologist / physiotherapist (22, 23);
- Quality of life assessment – nurse;
- Assessment for depression – psychologist.

As a result, standard programs strictly supervised and hospital-based limit the accessibility of PAH patients to this important therapeutic intervention - pulmonary rehabilitation. Under these circumstances, even 45-minute sessions of walking, six times a week, at 65-75% of the heart rate reserve, plus L-arginine supplementation 6 g/day to maximize endothelial adaptation to exercise, have positive effects on exercise capacity, demonstrated by increasing of the distance walked, comparative to baseline (24).

European Society of Cardiology guidelines recommend supervised exercise training in patients with PAH, physically deconditioned but clinically stable, and under

optimal pharmacological therapy (class II a recommendation, level of evidence B) (6, 7). However, the optimal duration, intensity, frequency, and type of exercise for these patients as well as the mechanisms of positive effects remain an issue with incomplete or unclear answers (1, 6, 7). Among the training methods, skeletal peripheral muscles and inspiratory muscles training results in improvement of muscle strength, maximal inspiratory pressure, and peak oxygen uptake, without notable adverse effects (22). Consequently, low-level graded endurance and resistance exercises, as well as inspiratory and peripheral muscles training, are recommended, along with careful patients' education regarding their own illness, nutrition, and safe level of physical effort (7, 25).

CONCLUSIONS

Our study concludes that the exercise intolerance is a major cause of disability and decreased quality of life in patients with pulmonary arterial hypertension so that, careful evaluation of the causes and mechanisms of this intolerance is very important. Improving health care for patients with pulmonary hypertension increases their longevity, educating the patient and multidisciplinary approach being key elements. Although there are no standardized training protocols, pulmonary hypertension rehabilitation programs have an acceptable safety profile, with few serious side effects and should be encouraged as part of the multidisciplinary management of this complex disease.

2. Spitalul Clinic de Urgenţe pentru Copii "Sf. Maria", Iaşi, Clinica a III-a Pediatrie

THE ETIOLOGICAL ASPECTS OF ACUTE ABDOMINAL PAIN IN CHILDREN (Abstract): **Aim:** The study of the etiological aspects of acute abdominal pain in children, in order to perceive the clinical-etiological correlations and the disorders distribution related to age, gender and the origin of the patients. **Material and methods:** The criteria for including patients were age (between 0 and 18 years) and the presence of acute abdominal pain before or during the consultation with the physician. The research on acute abdominal pain in children was performed on the level of the Surgery and Pediatrics II clinical departments of the „Sf. Ioan" Children's Emergency Clinical Hospital in Galati, between 01.01.2009 - 01.01.2011. The clinical study performed on the patients registered in the studied groups focused on the identification, the evaluation of the symptoms of acute abdominal pain in children, diagnosing and treating it. The criteria for excluding patients were an age older than 18 years or the absence of acute abdominal pain as a symptom before or during the examination. The statistical analysis used the descriptive and analytical methods. The data was centralized and statistically processed in *M.S.EXCEL* and *S.P.S.S.* databases. **Results:** The patients with acute abdominal pain represent a percentage of 92.9% (2358 cases) of the total number of patients who suffer from abdominal pain (N=2537). The highest frequency of cases is represented by acute appendicitis (1056 cases – 44.8%). In the 5-18 years age group, acute appendicitis, mesenteric lymphadenitis, ovarian follicular cysts, acute pyelenophritis and salpingitis are predominant. In the 0-4 years age group gastroenteritis, acute pharyngitis, reactive hepatitis and lower digestive bleeding are predominant. **Conclusions**: In females, acute appendicitis, gastroenteritis, gastroduodenitis and cystitis are predominant, whereas in males, peritonitis, sepsis through *E. coli*, the contusion of the abdominal wall and acute pharyngitis are predominant. **Key-words**: ACUTE PAIN, CHILD, ETIOLOGY.

Durerea este definită de International Association for the Study of Pain (I.A.S.P.) (1) drept "o experienţă senzorială şi emoţională dezagreabilă, dată de o leziune tisulară veritabilă sau potenţială sau de o descriere cu termeni ce se referă la o asemenea leziune". În funcţie de durata ei, durerea se poate împărţi în două mari categorii: acută şi cronică (2). Durerea abdominală acută este de scurtă durată, fiind caracterizată de bruschețe (3,4). Datorită impactului durerii acute asupra calităţii vietii, ne-am propus să studiem aspectele etiologice ale durerii abdominale acute la copil, pentru a observa corelaţiile clinico-etiologice şi distribuţia afecţiunilor în raport cu vârsta, sexul şi mediul de reşedinţă al pacienţilor.

MATERIAL ŞI METODE

Criteriile de includere ale pacienților au fost vârsta (între 0 şi 18 ani) şi prezența durerii abdominale acute, înainte sau în momentul prezentării la medic. Cercetarea durerii abdominale acute la copil a fost efectuată în secțiile de Chirurgie şi Pediatrie II ale Spitalului Clinic de Urgență pentru Copii „Sf. Ioan" Galați în perioada 01.01.2009-01.01.2011. Studiul a inclus un lot de 2358 pacienți, urmărind recunoaşterea, evaluarea, diagnosticarea şi tratarea durerii abdominale acute. Criteriile de excludere ale pacienților au fost vârsta mai mare de 18 ani sau lipsa durerii abdominale acute drept simptom, înainte sau în momentul examinării. Pentru realizarea bazei de date am primit avizul comisiei de etică a Spitalului Clinic de Urgență pentru Copii „Sf. Ioan" Galați. Toate datele medicale au fost prelucrate şi evaluate statistic, folosindu-se programe specifice, *SPSS 13.0* şi *Microsoft Office Excel*, utilizându-se un interval de încredere de 95% şi obținându-se rezultate cu prag semnificativ p = 0,05.

REZULTATE

Dintre cei 2537 pacienți internați cu durere abdominală şi incluşi în studiu, 2358 (92,9%) au prezentat durere abdominală acută. În relație cu structura etiologică a durerilor abdominale acute, am constatat că apendicita acută a înregistrat cea mai mare frecvența (1056 - 44,8%), fiind urmată de apendicita acută cu abces peritoneal (187 - 7,9%), gastroenterită (218 - 9,2%), gastroduodenita acută (203 - 8,6%), şi limfadenita mezenterică (125 - 5,3%), tabloul etiologic fiind completat de afecțiuni semnalate într-un număr redus (<5%) (fig. I).

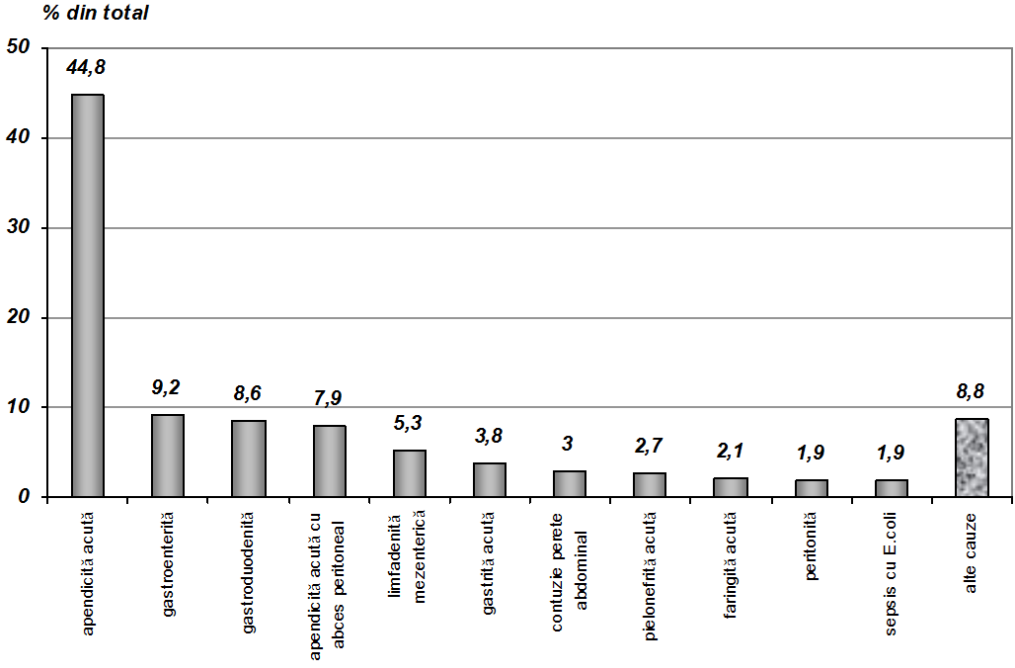

Fig. 1. Tabloul etiologic al copiilor cu durere abdominală acută

Repartiția pe grupuri de vârstă a cazurilor de durere abdominală acută a evidențiat un polimorfism etiologic semnificativ (tab. I, II).

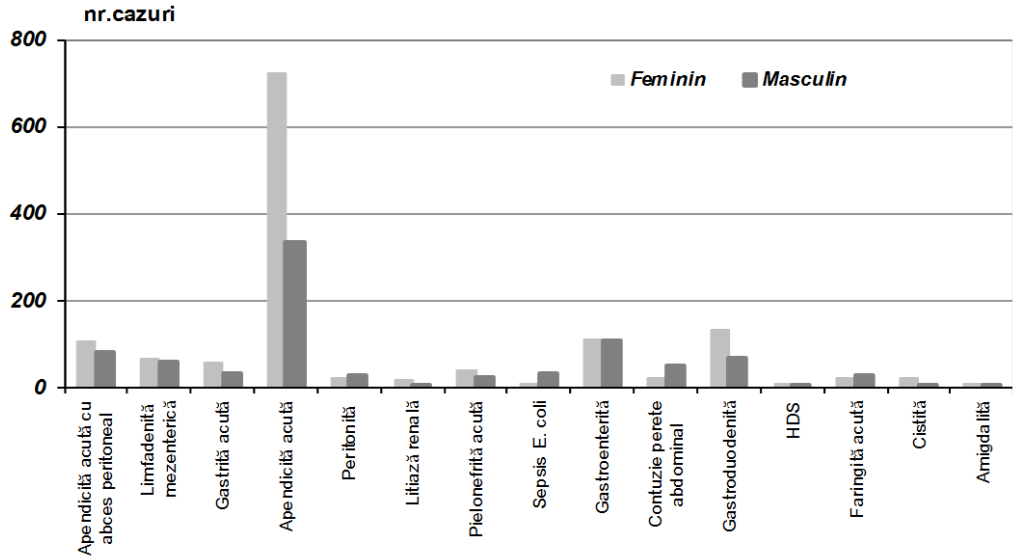

Fig. 2. Distribuția pe sex a pacienților, în relație cu etiologia durerii

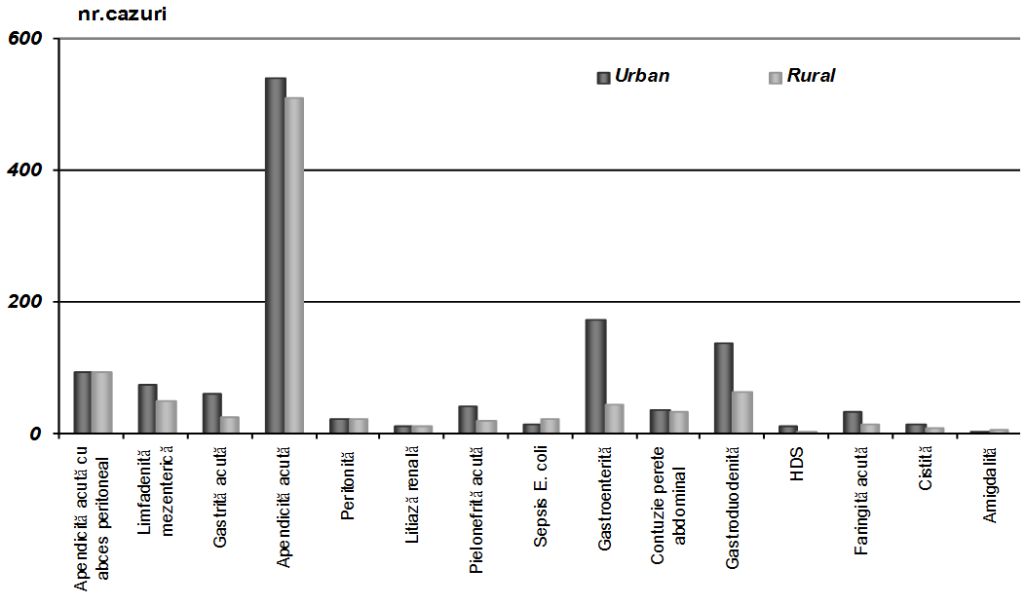

Fig. 3. Distribuția, pe medii, a pacienților, în relație cu etiologia durerii

Cercetările au evidențiat că durerea abdominală acută a fost înregistrată, cel mai frecvent, la grupul de vârstă 5-18 ani, în caz de apendicită acută, limfadenită mezenterică, chist folicular ovarian, pielonefrită acută şi salpingită, în timp ce la grupul de vârstă 0-4 ani, aceasta a fost prezentă în cadrul gastroenteritei, faringitei acute, hepatitei reactive şi hemoragiei digestive inferioare (tab. II).

La pacienții de sex feminin, s-a evidentiat frecvența crescută a următoarelor afecțiuni: apendicita acută, gastroenterita, gastroduodenita acută şi cistita, în timp ce la cei de sex masculin, a peritonitei, sepsisului prin *E. coli*, contuziei de perete abdominal şi a faringitei acute (fig. 2).

În relație cu mediul de reşedință şi etiologia durerii abdominale acute, s-a observat frecvența crescută a durerii abdominale acute la copiii proveniți din mediul urban, cu excepția sepsisului prin *E. coli* şi amigdalitei care au fost mai frecvente în mediul rural (fig. 3).

DISCUȚII

Studiile efectuate în România (5) arată că durerea abdominală acută la copil prezintă frecvent următoarea etiologie: apendicita acută, adenita mezenterică, gastroenterita, faringita, pneumonia de lob inferior drept, pielonefrita acută, abuzul alimentar.

Studiile efectuate în SUA (6,7,8,9,10) au evidențiat că apendicita acută, gastroenterita, limfadenita mezenterică, constipația şi traumatismul abdominal sunt cele mai frecvente afecțiuni care generează durere abdominală acută la copil. Detaliat, pe grupuri de vârstă, studiile (6,7,8,9,10) relevă că, la 0-1 an predomină colicile infantile, gastroenterita, constipația şi infecția de tract urinar; la 2-5 ani, gastroenterita, apendicita acută, constipația, infecția de tract urinar; la 6-11 ani, gastroenterita, apendicita acută, constipația, iar la 12-18 ani, apendicita acută, gastroenterita, constipația şi dismeno-

reea. Un studiu efectuat în Turcia (11) a arătat că apendicita acută este cea mai frecventă cauză de spitalizare a copiilor cu durere abdominală acută (44,1%), apărând la o vârstă medie de 11,2 ± 2,7 ani, mai frecvent la sexul masculin.

CONCLUZII

Studiul a evidențiat că apendicita acută estecea mai frecventă cauză a durerii abdominale acute la copil. La grupul de vârstă 0-4 ani, au predominat cazurile de gastroenterită, iar la 5-18 ani, cele de apendicita acută. În relație cu mediul de reședință al copiilor cu durere abdominală acută, s-a observat că sepsisul prin *E. coli* și amigdalita acută au fost mai frecvente în mediul rural, celelalte afecțiuni predominând la pacienții din urban. Datele obținute sunt în acord cu cele din literatură, evidențiindu-se existența unor variații geografice ale etiologiei durerii abdominale acute la copil.

2. Faculty of Dental Medicine,

RESPIRATORY INVOLVEMENT IN THE GASTROESOPHAGEAL REFLUX DISESEASE (Abstract)**:** The pathological gastroesophageal reflux disease may lead to the gastroesophageal reflux disease (GERD), manifested as a spectrum of conditions including erosive esophagitis, Barrett esophagus and has been linked to the development of adenocarcinoma of the esophagus. The gastroesophageal reflux has been incriminated in the occurence of a number of pulmonary symptoms and diseases, otolaryngologic symptoms, and other extraesophageal manifestations. Clinicians must be aware of the possibility of some extraesophageal reflux-related manifestations, even in the absence of heartburn and acid reflux, classic esophageal symptoms of GERD. Although the correlation between gastroesophageal reflux disease and the extraesophageal manifestations has been established, a cause-and-effect relationship has not been proved yet. In this article, we present the respiratory manifestations of gastroesophageal reflux disease, referring to epidemiology, pathogenesis, diagnosis and treatment. **Keywords**: BRONCHIAL ASTHMA, ESOPHAGITIS, GERD, LARYNGITIS, RESPIRATORY SYMPTOMS

The cardinal symptoms of gastroesophageal reflux disease (GERD) are heartburn and regurgitation. Heartburn is defined as a burning sensation in the retrosternal area, and regurgitation as the perception of flow of refluxed gastric content into the mouth or hypopharynx. Although the reflux of acid gastric content is usually responsible for the symptoms of GERD, non-acid reflux of substances such as bile may also be important in a minority of patients (1). It is extremely common that patients with GERD experience symptoms: approximately 20% of adults reporting heartburn, acid reflux or both at least once a week and approximately 40% reporting that such symptoms occur at least one a month (2).

The prevalence of GERD is estimated to be 10% to 20% in Europe and North America and at least 5% in Asia (3). The need for a patient-centered, symptom-driven approach to GERD assessment and diagnosis was addressed in the Montreal definition and classification published in 2006. Developed by an expert consensus group consisting of 44 primary and secondary care physicians from 18 countries, the Montreal definition is built on evidence-based medicine and systematic literature reviews. Montreal definition includes a measure of symptom severity by stating that GERD is "a condition which develops when the reflux of stomach contents causes

troublesome symptoms and/or complications"(4).

Classic reflux symptoms are not always present in patients with GERD. A significant number of patients with GERD present with atypical or extraesophageal symptoms. It has been shown that GERD is associated with pulmonary symptoms, as well as with lower airway diseases (asthma, chronic cough, bronchitis, aspiration pneumonia and idiopathic pulmonary fibrosis), otorhinolaryngologic signs/symptoms (hoarseness, laryngitis, subglottic stenosis, vocal cord granuloma and laryngeal carcinoma) and other extraesophageal manifestations (noncardiac chest pain, dental erosion, sinusitis, pharyngitis and sleep apnea) (5). Classic reflux symptoms are absent in 40 to 60 percent of patients with asthma, 57 to 94 % of patients with ear, nose, and throat symptoms, and 43 to 75% of patients with chronic cough in whom reflux is suspected as the primary etiology (6). Therefore, GERD should be strongly considered in the differential diagnosis of patients presenting with atypical symptoms when alternative diagnoses have been excluded (7).

Pathogenesis of respiratory symptoms in GERD

Two possible mechanisms have been proposed as underlying GERD-related extraesophageal symptoms: the microaspiration of gastric content into extraesophageal structures during reflux episodes and the stimulation by the gastric refluxate of a vagal reflex arch extending from the esophageal body to the bronchopulmonary and laryngeal systems (8).Both mechanisms have been supported by clinical and laboratory data documenting the injurious effects of esophageal acid on extraesophageal structures.

There are some defense mechanisms protecting against extraesophageal complications of GERD: junctional structures at the gastroesophageal interface include the lower esophageal sphincter, the crural diaphragm, the sling fibers, and the phrenoesophageal ligament. In addition to these potential pharyngoglottal mechanisms, intrinsic laryngeal reflex mechanisms play an important role in limiting the spread of aspirate and enhancing clearance. Such mechanisms would include the cough reflex and mucociliary action of the bronchotracheal surface (8). Any disfunctions in this defense mechanisms can lead to extraesophageal complications of GERD.

Diagnosis

Currently upper gastrointestinal endoscopy is the main clinical tool for visualizing esophageal lesions. Since the majority of GERD patients do not have endoscopic visible lesions other methods are required to document the abnormal acid exposure in the distal esophagus. For many clinicians ambulatory esophageal pH monitoring is the gold standard in diagnosing GERD since it quantifies distal esophageal acid exposure and allows the evaluation of the relationship between symptoms and acid reflux. Impedance is a new technical development that offers unexplored possibilities for investigating GERD. It allows the detection of the frequency, the height , and duration of reflux episodes independent of the pH of the refluxate (9). Combined with pH multichannel intraluminal impedance and pH (MII-pH) monitoring has become a clinically available tool which can detect gastroesophageal reflux independent of pH (10). This new techniques can quantify exposure to esophageal acid and identifying reflux events regardless of acidic

content to assess correlations with symptoms (11). The diagnostic sensitivity of multiple intraluminal impedance may correspond to that of the pH probe in untreated patients but is superior to the pH probe in patients treated with antacid medication (12). The availability of highly selective gastric acid suppressive therapy led to the introduction of short trials of PPI to diagnose GERD. PPI trials are often used as a first line diagnostic tool in clinical practice and in particular in the primary care settings (13).

Respiratory conditions

Bronchial asthma

Asthma is the pulmonary disorder most often associated with GERD, and acid reflux disease is found in 30% to 89% of asthmatics (14). Some studies have established not only the co-existence, but also the cause-and-effect relationship, establishing GERD as one of the significant causes of asthma in adults.

Two mechanisms have been incriminated in the pathogenesis of GERD-related asthma: microaspiration of the refluxed gastric contents and esophagobronchial reflex triggered by the stimulation of vagal receptors in the distal third of the esophagus. Through the mechanism of microaspiration, the pulmonary symptoms would result from the direct aggression of acids and enzymes present in the reflux gastric contents on the respiratory mucosa, thereby leading to reflex bronchospasm. On the other hand, some authors have suggested that the prevalence of GERD is higher in patients with chronic obstructive pulmonary disease, indicating that altered respiratory mechanics predisposes to GERD (15). Physiological alterations in asthmatic patients, such as increased intrathoracic pressure and hemidiaphragm rectification could debilitate the antireflux barrier and consequently predispose to GERD. Regarding the medication used in the control of asthma, some might favor reflux medications, such as theophylline and adrenergic beta-agonists, because they relax the smooth muscles of the esophagus and stomach (16). However, such medications cause reduced esophageal clearance capacity and delayed gastric emptying, resulting in a proreflux effect, especially in patients with mechanical defects of the lower esophageal sphincter.

The most commonly used exams for the diagnosis of GERD-induced asthma is the 24-h pHmetry but it presents less than satisfactory sensitivity and specificity, despite identifying and quantifying the pathological acid reflux, presents a high rate of false-negative results. Therefore, the 24-h pHmetry is only indicated for patients who did not respond to empirical treatment with acid secretion inhibitors (17). Endoscopy of the upper digestive tract remains an important exam in the evaluation of GERD. It makes possible the confirmation of the diagnosis, as well as detection of complications of the disease. Similarly, contrast-enhanced radiological examination of the esophagus, stomach and duodenum can detect alterations, although only in more advanced cases. However, these exams are incapable of objectively demonstrating the causal relationship between pathological acid reflux and respiratory symptoms (5). The empirical treatment used in the diagnosis of uncomplicated GERD is a good strategy for the evaluation of patients with GERD-induced asthma since it is relatively simple, inexpensive, and without the discomfort of invasive tests (18). In a cost-effectiveness analysis of the available di-

agnostic strategies it was concluded that the most cost-effective approach is empirical therapy with proton pump inhibitors (PPIs), such as omeprazole at 20-40 mg/day for three months. Therefore, the initial step in the diagnosis of GERD-induced asthma should be empirical treatment to suppress acid with a PPI (17).

In patients with uncomplicated GERD and presenting typical symptoms, the response to both clinical and surgical treatments, has been excellent (19). However, the therapeutic response in GERD patients presenting extra-esophageal symptoms is not very clear. Here is a study that evaluated 30 patients with asthma and GERD with the objective of determining the dosage and duration of omeprazole treatment needed to reduce respiratory symptom severity. The patients initially received a three-month course at 20 mg/day. From the fourth month onward, the dose was progressively increased until acid suppression, documented by 24-h pHmetry, occurred. In 73% of the patients, respiratory symptom severity was reduced or peak expiratory flow increased. In 57%, there was a significant reduction in symptom severity by the end of the third month of treatment. The mean omeprazole dose needed to obtain acid suppression was 27 mg/ day (20). On the other hand in their article on the use of esomeprazole in patients with poorly controlled asthma Mastronarde et al. conclude that treatment with proton-pump inhibitors does not improve asthma control in such patients (21).Although the use of proton-pump inhibitors diminishes the acidity of the reflux, it does not reduce either the number or proximal extent of reflux events, microaspiration and esophageal reflexes may still contribute to airway inflammation in patients with asthma who are receiving a high-dose proton-pump inhibitor, and this may be the explanation for the poor control of asthma manifestation (22). An alternative explanation for the lack of efficacy of esomeprazol is related to bacterial overgrowth in the stomach, promoted by acid suppression. A gastric pH of more than 4 favors the growth of predominantly gram-negative bacteria in the stomach (23). Although proton-pump inhibitors reduce the volume and acidity of gastric contents, they do not prevent pulmonary micro-aspiration. Recurrent microaspiration of bacteria enriched gastric contents might have sustained lung inflammation in the group of patients with poorly controlled asthma. Starting from this hypothesis it appears the interesting idea that bacterial colonization of the gastric contents and microaspiration in patients who are receiving proton-pump inhibitors might lead to worsening asthma. There were not found any convincing evidences that the use of proton-pump inhibitors leads to an increase in the rate of pneumonia or worsening of asthma. However, it is possible that there was a balanced trade-off between beneficial effects and harmful effects of acid suppression.

Since the causes of GERD are predominantly mechanical, the correction of the antireflux barrier through antireflux surgery controls two of the main etiological factors of GERD: the defective lower esophageal sphincter and the hiatal hernia. The currently recommended surgery is laparoscopic fundoplication.

It makes it possible to maintain the gastroesophageal junction in intraabdominal position and build a valve with the gastric fundus, safely re-establishing gastric cardia competence through the mechanical improvement of its function.

A group of authors conducted an in-

depth review of the literature analyzing the effects of the antireflux surgery on the symptom severity and the pulmonary function in patients with asthma and GERD. Of the 417 patients included in the analysis, a significant reduction in GERD symptom severity was obtained in 90% and in asthma symptom severity in 79%. In addition, 88% decreased their use of bronchodilators, and 27% presented improvement in their pulmonary function test results. The authors concluded that, although it has little effect on pulmonary function test results, antireflux surgery can significantly reduce GERD-related respiratory symptom severity and decrease the need for asthma control medications (24).

According to other studies evaluated respiratory symptoms in patients with GERD initially treated with a PPI and later with antireflux surgery, after six months of PPI treatment, respiratory symptom severity decreased in only 14% of the patients, and none of the patients remained asymptomatic during this period. After laparoscopic fundoplication, respiratory symptom severity decreased in 86% of the patients, and 67% remained asymptomatic until the end of the study. The results of these studies suggest that clinical treatment with a PPI should be the initial approach to GERD-related asthma. Surgical treatment is indicated for patients with GERD, especially for those who are under 50 years of age, who do not satisfactorily respond to clinical treatment, who suffer recurrence of symptoms within four weeks after the discontinuation of PPI therapy or who require continuous maintenance treatment with PPI (25,26).

Laryngitis

Laryngitis is the most common otorhinolaryngologic disease that has been associated with GERD (27). Although the prevalence of reflux laryngitis is unknown, it is estimated that 4% to 10% of the patients who seek the assistance of an otorhinolaryngologist present GERD-related symptoms or findings (28). It has been also shown that a significant portion of patients with laryngeal manifestations of GERD, including reflux laryngitis, do not present the typical symptoms of GERD (27).

Most gastroenterologists consider laryngopharyngeal reflux as an extraesophageal manifestation of GERD, while otolaryngologists belive laryngo-pharyngeal reflux and GERD are two completely different disease entities with different mechanisms and clinical manifestations

The symptoms of reflux laryngitis are nonspecific and cannot be differentiated from the symptoms of laryngitis with other causes. Hoarseness is the most common symptom; other symptoms can include cough, throat clearing, odynophagia, altered voice, globus and dysphagia. Laryngopharyngeal reflux is considered a causative role in 60% to 70% of the Western population with globus, hoarseness, chronic cough and frequent throat clearing (29-31). Symptoms such as globus or frequent throat clearing may be also caused by other factors such as smoking, voice abuse or allergy.

Laryngoscopy plays a fundamental role in the evaluation of chronic laryngitis. The classical abnormality described in reflux laryngitis is 'posterior laryngitis', which consists of the thickening of the mucosa accompanied by edema and erythema of the arytenoids. But none of those modifications are not specific to reflux laryngitis, arytenoid erythema and subglottic edema also can be found in healthy population.

The documentation of pathological gastroesophageal reflux is appropriate in some patients, particularly in those with symptoms refractory to PPI treatment. Currently, doublechannel esophageal and pharyngeal outpatient monitoring of esophageal pH is considered the most sensitive means of diagnosing laryngo- pharyngeal reflux (32).

Relating to treatment there are a lot of studies to evaluate the efficacy of PPI in patients with laryngopharyngeal reflux related to GERD. One study (33) evaluated 45 patients with possibly GERD-related otorhinolaryngologic symptoms. Patients were treated for two months with 20 mg of omeprazole twice a day or 30 mg of lansoprazole twice a day. The authors found that 47% of the patients presented improvement after two months, increasing to 64% after four months. The authors concluded that empirical treatment with PPI twice a day for four months is efficacious in the identification and treatment of most patients with otorhinolaryngologic symptoms caused by GERD. Unfortunately, six months after the discontinuation of PPI therapy approximately 80% of the patients suffer symptom recurrence.

An other study evaluated 82 patients with GERD and laryngopharyngeal reflux. It was tested rabeprazole efficiency in high doses (20mg twice daily) compared to placebo. It showed significant improvements in laryngopharyngeal reflux- related symptoms with high-dose rabeprazole within 12 weeks of PPI treatment in comparison with placebo. Relapse of symptoms was observed 6 weeks after stopping PPI therapy, indicating the requirement for longer treatment duration in patients with laryngopharyngeal reflux (34). Some sudies, comparing PPI treatment with placebo , showed similar response to both therapys , which suggest that other nonorganic factors such as anxiety and depression also may contribute to laryngo- pharyngeal reflux symptoms (35, 36). For example, patients with anxiety and depression were found to be more prone to exaggerate physical symptoms related to their laryngopharyngeal reflux conditions.

Antireflux surgery is effective in most patients with reflux laryngitis (37). Laparoscopic Nissen fundoplication have shown a response rate of over 70% among patients with GERD-related otorhinolaryngologic symptoms. It has been also proven that successful laparoscopic fundoplication is more cost-effective than is high-dose, long-term suppression therapy with a PPI (38). In conclusion the first-line treatment in patients with laryngo-pharyngeal reflux is the use of a PPI in moderate doses (e.g. omeprazole at 40 mg/day) for a minimum of three months. In case of recurrence of symptoms after this period, the reflux should be confirmed through complementary exams (24-h pHmetry) and the feasibility of performing laparoscopic fundoplication should be evaluated.

Chronic cough

Cough is the most common symptom for which patients seek medical attention (39).It is defined as persistent cough for a minimum period of eight weeks. Chronic cough is estimated to affect 11-20% of the population (40) which means it has a significant socioeconomic impact (41) and an important reduction in quality of life (42).

Patients with chronic cough accompanied by GERD present a typical profile that includes being a nonsmoker, presenting a normal chest X-ray and not using angiotensin-converting enzyme inhibitors.

Convergence of vagal afferents from the esophagus and respiratory tract in the brain suggested the idea of a possible esophageal-bronchial reflex. This is supported by the findings that acid infused into the distal esophagus of patients with chronic cough increased the frequency of coughing and cough reflex sensitivity (43). Sensitization of a central mechanism might explain why the reflux that was mainly confined to the distal esophagus appears temporally associeted with cough in a significant proportion of chronic cough patients in whom non-GERD causes were excluded (44). One study (45) evaluated the relation between cough and reflux. Twenty-four hour ambulatory acustic cough monitoring with simultaneous impedance/pH recording was carried out in 71 unselected patients with chronic cough. The results shown that 70% of patients exhibited temporal association, 48% having a positive symptom association probability for cough preceded by reflux, 56% a positive symptom association probability for reflux preceded by cough, and 32% both. In conclusion the study shown that irrespective of possible underlying cause reflux can temporally associate with cough. The lack of association with proximal extent of reflux and erosive disease, but link to increased cough reflex sensitivity, suggest that a sensitized central mechanism may be facilitating reflux-induced cough and cough-induced reflux.

Referring to the treatment of chronic cough associated to GERD most studies have shown that both clinical and surgical treatments are efficacious in reducing cough. One such study shown that a 4- to 6-week course of omeprazole at a dose of 40 mg, alone or combined with prokinetic agents (metoclopramide or cisapride) reduced GERD-related cough in 80% of the patients studied (46). Irwin et al, analyzing surgical treatment (laparoscopic Nissen fundoplication) of GERD-related chronic cough in adults, demonstrated a 100% response to treatment in two studies and a 56% to 85% rate of favorable response in another four studies (47). Currently, effective antitussive drugs are unavailable, and, although a number of agents have been shown to reduce transient lower esophageal sphincter relaxation, these have not been assessed in chronic cough (48). The first-line approach in the GERD-related cough is the PPI therapy even if a significant proportion of patients present recurrence of symptoms immediately after discontinuation of the treatment. The poor efficacy of traditional drugs, such as those targeting gastric acidity, may be explained by the presence of a sensitized central mechanism which facilitate reflux-induced cough and cough induced reflux.

GERD in lung transplanted patients

Patients with lung transplantation present alteration of gastrointestinal motiltiy. GERD is present in patients with chronic lung disease but may be encountered also after lung transplantation (49). GERD is connected to obliterative bronchiolitis, a factor causing rejection in lung transplantation (49). Preventing reflux in lung transplantation is improving the survival (50).

Oral changes

Respiratory involvement is not isolated in GERD. The refluxate may arrive in the oral cavity and produce there oral and dental alterations. Specific tooth erosion is generally associated with GERD symptoms. The importance of tooth loss is correlated to regurgitation frequency, and acid

pH oral modifications (51, 52). Therefore carefully teeth examination should be done in GERD with respiratory symptoms. The presence of glossitis has also been reported in GERD (53).

CONCLUSIONS

Extraesophageal manifestations of GERD constitute a heterogeneous disease group, but even so, some general characterizations can be made.

The diagnosis can be difficult because of the great prevalence of 'silent GERD' in the population. Acid reflux should be considered if signs of GERD are present, if extraesophageal symptoms are unexplained, or if these symptoms are refractory to treatment.

Traditional exams, such as endoscopy of the upper digestive tract and contrast-enhanced radiological examination of the esophagus, stomach and duodenum, can be useful in the diagnosis of GERD and are still important tools for the detection of esophageal complications. However, these exams might not confirm GERD, and they do not establish a causal relationship between GERD and extraesophageal symptoms. The most sensitive exam is the 24-h pHmetry, which is considered the gold standard in diagnosing GERD , and it plays an important role in the evaluation of patients with extra-esophageal manifestations. Nevertheless, 24-h pHmetry might not confirm the causal relationship between GERD and the extraesophageal symptoms. Therefore, the empirical test with PPI therapy can be useful in establishing the diagnosis. Atypical manifestations generally require more aggressive and longer-term antisecretion therapy than do typical GERD symptoms.

THE DEPRESSION AND THE CARDIOVASCULAR DISEASES IN THE ELDERLY (Abstract): The aim of this study was to reveal if there are connections between depression and cardiovascular disease. **Material and method**: We have studied 413 patients from Jorasti, Jud Galati on a two-years period (2008-2010). On these patients there was performed a careful history taking and they were physically examined (height, weight, body mass index, waist, blood pressure, heart rate). There was also performed an ECG (electrocardiogram), there were measured the levels of cholesterolemia, HDL-cholesterolemia, trygliceridemia and creatininemia. We used the Geriatric Depression Scale (GDS) in order to evaluate depression. **Results:** in these patients there was noticed a higher prevalence of dyslipidemias, obesity and depression in women. Out of the 46 women with mild and severe depression 32 are overweight, 7 have obesity, 29 a high cholesterol, 23 a high LDL-cholesterol; all of them had a high risk or the presence of cardiovascular disease. **Conclusions:** Depression is an independent risk factor for producing a cardiovascular event; the level of cholesterol and of the blood preessure was higher in patients with severe depression, proving that the level of the cardiovascular risk factors increased with the severity of the depression. Treating the elderly, which often associate depression, makes necessary a careful evaluation of all comorbidities and risks, in order to establish perfect individualized strategies of improving the quality of life. **Key words**: CARDIOVASCULAR DIASEASE, DYSLIPIDEMIA, DEPRESSION

Depresia este o tulburare mentală caracterizată printr-o modificare profundă a stării timice, a dispoziției, în sensul tristeții, al suferinței morale şi încetinirii psihomotorii, asociindu-se în general cu anxietatea. Ea întreține la pacient o impresie dureroasă de neputință globală, de fatalitate disperată, iar uneori antrenează ruminații subdelirante pe tema culpabilității, a indignității, a autoaprecierii, putând conduce la luarea în considerare a sinuciderii şi uneori, la realizarea acesteia (1). Sentimentul de inutilitate, de culpă poate cuprinde aprecieri negative asupra propriei valori care nu corespund realității. Tulburarea depresivă este legată de regresie, în aspectele ei de regenerare şi îmbogățire, în particular ea poate lua forma golului lipsit de viață, în asemenea circumstanțe noua dezvoltare este cea care a sustras energia din conştiință conducând la depresie (2). După Kielholz, sindromul depresiv constituie o

modalitate de reacție de bază la diferite condiții şi situații cu efect somatogen, psihogen sau endogen şi care se manifestă prin triada dispoziție depresivă, inhibiție psihomotorie şi afectarea funcțiilor psihomotorii (3).

Evoluția depresiei variază de la o persoană la alta. Pot fi prezente simptome uşoare sau severe de depresie, pentru o perioadă îndelungată de timp sau pentru o perioadă scurtă. Un procent mic de persoane se simt depresive în marea majoritate a vieții lor; acestea necesită un tratament de întreținere.

În cazurile severe de depresie, persoana respectivă poate ajunge la incapacitatea de a comunica, la incapacitatea de a efectua activitățile de rutină şi chiar la suicid. În aceste cazuri, consultul unui specialist şi urmarea unui tratament sunt esențiale.

Aspecte clinice ale relației riscului de boală arterială coronariană urmare a bolii depresive

Boala arterială coronariană este considerată ca fiind cauza principală de deces atât pentru bărbați cât şi pentru femei. Între cauzele care generează acest fenomen se numără şi factorii psihosociali care sunt implicați atât în etiologia, progresia cât şi prognosticul acestor evenimente (3). Cercetări recente sugerează că depresia este un indicator psihosocial particular de puternic, pentru deces în evoluția bolii arteriale coronariene.

Dovezi preliminare care susțin relația dintre depresie şi boala arterială coronariană (CAD) au fost furnizate de studii efectuate pe pacienți cu patologie ischemică coronariană, studiile respective au scos în evidență o prevalență disproporționat de mare a depresiei la pacienții cu boală ischemică coronariană față de (comparativ cu) populația generală. Astfel, prevalența depresiei la bolnavii cu patologie ischemică coronariană este între 19%-47% față de 4%-7% în populația generală, ceea ce a sugerat ideea că depresia ar putea contribui la apariția şi dezvoltarea bolii coronariene ischemice (4). Literatura medicală abundă în lucrări pe această temă, care în studii pe loturi mari de bolnavi obiectivează această idee în procentaje care variază de la autor la autor.

Tulburări somato - psihice ale bolnavilor cardiaci

Tabloul manifestărilor clinice psihosomatice propriu-zise este destul de bogat, de aceea vom aborda manifestările clinice unde raportul factor psihic - răsunet somatic este evident, ordonându-le astfel:

- simptome şi semne psihosomatice ca reacții normale la tensiuni psihice,
- tulburări psihosomatice ca dezvoltări psihofuncționale,
- boli psihosomatice ca organizări psihosomatice.

Manifestările psiho-somatice cardiovasculare sunt aproape o regulă în stările anxioase sub forma cenestopatiilor cardiace care pun reale probleme de diagnostic diferențial şi terapie, influențează calitatea vieții devenind uneori FR de mortalitate.

Simptome şi semne psihosomatice: reprezentate de manifestări clinice, componente normale asociate emoțiilor, care durează puțin şi sunt rapid reversibile.

Tulburări de ritm:

a) Tahicardiile şi bradicardiile regulate induse psihogen au la bază corelarea frecvenței cardiace cu reflexele de apărare sau de orientare către un stimul.

b) Extrasistolele (ES) reprezintă cea mai frecventă tulburare de ritm apărută în cursul SP.

c) Fibrilația atrială (FA) Riscul de atac vascular cerebral (AVC) al pacienților cu

FA este de 4,5% pe an. Episoadele tranzitorii de FA paroxistică, apărute în cadrul unui SP, sunt estimate la circa 3%. (5)

Tulburări de conducere. Sunt reprezentate de lărgirea complexului QRS şi scurtarea amplitudinii acestuia. Aceste valori ating în cursul unei excitaţii provocatoare de spaimă, 0,07 secunde şi, respectiv 1,38 mV, comparativ cu traseul de bază (0,01 secunde şi respectiv 1,68 - 1,83 mV) (3).

Dureri precordiale. Durerea toracică este un simptom ce caracterizează atât bolile organice, cât şi cele funcţionale. Peste jumătate dintre pacienţii cu durere precordială care se prezintă la medicul cardiolog sunt "non cardiaci".

Durerea precordială este un simptom relativ frecvent la pacienţii anxioşi.

Dispneea „cardiacă". Dispneea, simptom cardinal al bolilor cardiace şi respiratorii este frecventă la pacienţii cu anxietate. Acest simptom poate să apară brusc, fără nici o legătură cu un efort fizic şi în prezenţa unei frecvenţe normale a respiraţiei, gazele sangvine fiind evident normale.

Variaţii ale tensiunii arteriale. Reacţia catecolaminică de stres generează răspunsuri hipertensive chiar la subiectul normal

Modificări vasomotorii în diferite teritorii. Acestea pot fi apreciate direct prin observaţie (eritemul pudic, paloarea din stările de spaimă, groaza, sau din crizele vasospastice de tip Raynaud, opusă expresiei fizionomice de "roşu la mânie".

Importante sunt stările lipotimice produse de ischemia cerebrală apărută în cursul unui SP, soldat fie cu un răspuns hipotensor, fie cu diferite tulburări cardiovasculare menite să scadă irigaţia cerebrală (de exemplu tulburări paroxistice de ritm).

Tulburări psihosomatice. În acest caz modificările clinice survenite sunt mai ample ca intensitate şi durată şi sunt mai bine structurate (6).

Sindromul cardiac hiperkinetic

Acest sindrom pune în evidenţă vagi tulburări cardiace şi multe simptome paralele autonome. Pacienţii se simt slăbiţi, forţele lor scad şi unii îşi simt inima bătând mai rapid. Spre deosebire de forma fobică a nevrozei cardiace, anxietatea e totuşi rară şi frica de moarte mai rar întâlnită.

Tahicardia paroxistică supraventriculară (TPSV)

În vreme ce în nevroza cardiacă şi în sindromul cardiac hiperkinetic se consideră că tulburările sunt psihogene, această suferinţă cardiacă evidenţiază situaţia în care factorii de stres fiziogeni şi psihogeni apar simultan şi se completează reciproc. În TPSV există o predispoziţie la crize datorită particularităţilor inervaţiei autonome a atriilor. Deşi lipsite de pericol prin ele însele, extrasistolele supraventriculare şi ventriculare, împreună cu încordarea emoţională, pot în cele din urmă să producă întreaga configuraţie de simptome.

Hipotensiunea arterială primară

Legătura dintre hTAE şi SP este sugerată de caracterul de "sindrom" al afecţiunii în cadrul căreia TAS este < 100 mm Hg şi TAD < 60 mm Hg, fiind asociată cu o serie de alte simptome cu substrat psihopatologic: fatigabilitate, astenie, cefalee, vertij, irascibilitate, transpiraţii, labilitate afectivă etc, fapt ce a făcut pe unii autori să vorbească mai degrabă de un "sindrom al hipotensivului" (7).

Astenia neurocirculatorie (ANC). Pacientul prezintă simptome subiective dominate de palpitaţii şi dureri precordiale, însoţite de un substrat organic. În privinţa conţinutului simptomatic al sindromului, este de subliniat frecvenţa cea mai crescută (la peste 70% din bolnavi) a dispneei (78%), ameţelilor (78%) şi cefaleei (72%).

Simptomele subiective cardio-vasculare şi respiratorii sunt prezente, de regulă, concomitent.

C. Boli psihosomatice - Acestea permit înțelegerea raporturilor de coordonare şi subordonare a elementelor constitutive ale bolii: agentul psihosomatogen, personalitatea premorbidă, predispoziția de organ, amorsarea patogenă, imprimarea morfofuncțională, relevanța clinică, evoluția, terapia. Ceea ce pune eticheta de boală psihosomatică este evidențierea substratului organic şi strângerea manifestărilor clinice în entități bine conturate.

a) Hipertensiunea esențială

Studiul Framingham privind sistemul cardiovascular, aflat în desfăşurare încă din 1948, a publicat în Lancet (2004) un ultim raport în care arată că riscul de apariție a unei HTA autentice este asociat cu valorile inițiale ale TA şi cu vârsta. O analiză a altor eventuali FR ai instalării HTA a confirmat rolul greutății corporale, creşterea cu 5% a acesteia (4 kg pentru un bărbat şi 5 kg pentru o femeie de constituție medie) asociindu-se cu o creştere cu 20-30% a riscului de dezvoltare a HTA.

MATERIAL ŞI METODĂ

Lotul de studiu a cuprins un număr de 413 pacienți din mediul rural care s-au prezentat la C.M.I. Dr. Anghel Lucreția-Jorăşti.

Evaluarea pacienților s-a făcut prin:

I Anamneză – a cuprins întrebări privind:

1. vârsta, sexul, starea civilă, nivelul de instruire, ocupaţia;

2. antecedente heredo-colaterale: deces prin boală cardiovasculară sub 55 de ani, cancer diagnosticat sub 65 de ani, diabet zaharat, hipercolesterolemie familială;

3. antecedente personale patologice: existenţa de boli cronice, boli cu transmitere sexuală, intervenţii chirurgicale, medicație relevantă;

4. stilul de viaţă: alimentaţia, consumul de alcool, activitatea fizică, fumatul.

II. Examenul clinic obiectiv – inclusiv măsurarea înălţimii şi a greutăţii, a taliei, calcularea indicelui de masă corporală, măsurarea tensiunii arteriale (3 valori la interval de 5 minute) şi a pulsului.

III. Investigațiile au cuprins:

- Electrocardiograma;
- Analize de laborator: glicemie, colesterolul total, HDL-colesterol, trigliceride, creatinina serică, sideremie.

Pentru determinarea depresiei la lotul de pacienți am folosit Scala Depresiei Geriatrice YESAVAGE (GDS).

REZULTATE ŞI DISCUȚII

În urma analizelor efectuate am constatat că dintre cele 242 de femei cu vârsta peste 60 de ani: 67 de femei sunt cu boală cardiovasculară prezentă iar 72 de femei sunt cu risc crescut de boală cardiovasculară, restul de 103 fiind cu risc scăzut sau fără risc de boală cardiovasculară. Ţinând cont de valoarea normală a colesterolului total (120,00-200,00 mg/dl) şi de IMC (Interval normal - 20 - 24,9; Supraponderalitate, risc crescut - 25 şi peste; Obezitate, risc mare - 30 şi peste)

Menționez că: din aceste 242 de femei 159 sunt cu hipercolesterolemie, 96 sunt supraponderale, 44 prezintă obezitate, 39 de femei prezintă depresie uşoară şi 7 sunt cu depresie severă.

Dintre cei 171 de bărbați cu vârsta peste 60 de ani 43 de bărbaţi sunt cu boală cardiovasculară prezentă iar 86 sunt cu risc crescut de boală cardiovasculară, restul de 42 fiind cu risc scăzut sau fără risc de boală cardiovasculară.

Din cei 171 de bărbaţi 86 sunt cu hipercolesterolemie, 68 sunt supraponderali, 19 prezintă obezitate, un bărbat prezintă depresie uşoară şi unul depresie severă.

Dintre cele 46 de femei cu depresie uşoară şi severă se observă că un număr de 32 sunt supraponderale, 7 prezintă obezitate, 29 prezintă colesterol total crescut, 23 prezintă LDL - colesterol crescut şi toate sunt cu risc crescut de BCV sau cu afecţiune prezentă.

Cei 2 bărbaţi cu depresie uşoară şi severă prezintă şi celelalte afecţiuni.

Din repartiţia pe sexe a valorilor medii a celorlalte afecţini se observă că femeile prezintă valori mai mari decât bărbaţii atât în ceea ce priveşte IMC, colesterol total cât şi depresia iar barbaţii prezintă risc mai mare de boală cardiovasculară.

Din lotul de pacienţi studiaţi (413) majoritatea (88,37 %) prezintă un scor mediu al depresie de 7,4 încadrându-se în limite normale, restul de 11,63 % prezintă depresie uşoară şi severă.

CONCLUZII

Depresia este un factor de risc independent de producere a unui eveniment cardiac.

Deşi nu este obiectivul acestui studiu să recomande tratamentul depresiei pentru reducerea riscului cardiovascular, depresia este prezentă în procentaj mare în rândul populaţiei şi trebuie cu siguranţă să fie tratată chiar şi numai datorită îngrijorărilor privind calitatea vieţii.

Depresia, boala cardiacă ischemică şi relaţia lor cu colesterolul este una controversată.

Depresia ar putea duce la un profil nefavorabil al lipidelor rezultat dintr-o interacţiune a axelor catecolaminice şi steroide.

Alături de factorii de risc cardio-vascular, stresul psihic (factorii psiho-sociali, socio-profesionali, socio-familiali) are un rol extrem de important în declanşarea patologiei.

Dintre factorii de risc modificabili, cu importanţă în declanşarea şi evoluţia HTA şi sindromului depresiv remarcăm: stilul de viaţă negativ (sedentarismul, comportamentul adictiv de alcool, nicotina, cafea, obiceiurile alimentare nesănătoase, abuzul de sare) şi caracteristicile individuale (valorile oscilante ale tensiunii arteriale, indicele de masă corporală), obezitatea abdominală, toate acestea fiind asociate cu TA crescută.

Nivelul factorilor de risc cardiovasculari convenţionali asociaţi bolii depresive şi-au sporit valoarea în relaţie directă cu gravitatea depresiei, astfel în formele majore de depresie şi nivelul colesterolului şi valorile presiunii arteriale au fost mai mari în medie, ceea ce a dus la creşterea poverii riscului absolut de boală cardiovasculară.

Abordarea persoanei vârstnice presupune cunoaşterea şi determinarea riscurilor geriatrice cu scopul elaborarii de intervenţii la nivel individual concretizate prin servicii de îngrijire care vizeaza îmbunătăţirea calităţii vieţii şi la nivel populaţional sub forma politicilor de sănătate care vizează prevenţia şi o îmbătrânire de succes.

HIGH LEVELS OF STERIGMATOCYSTIN IN PATIENTS WITH CHRONIC LIVER DISEASES (Abstract). Sterigmatocystin (STC) is a wide spread mycotoxin produced by *Aspergillus* fungi, with hepatotoxic and carcinogenetic proprieties. **Objectives:** To determine the STC concentration in blood and urine from patient with liver cirrhosis (LC) and hepatocellular carcinoma (HCC), with correlation with liver function parameters. **Material and methods:** The study enrolled 166 patients divided in three groups: control – 55 patients (27M, 28F); LC – 58 patients (31M, 27F); HCC – 53 patients (26M, 27F). 20 ml of blood and 50 ml of urine were collected from each patient and liver enzymes and alfa-fetoprotein (AFP) were measured. STC was determined by high performance liquid chromatography, with concomitant detection in ultraviolet and fluorescence. **Results:** STC was detected in 26.2% of samples, more frequently in LC and HCC groups ($p < 0.001$). STC mean values were 0.014 ng/ml and 0.005 ng/ml in blood, respective urine of controls, rising to 0.626 ng/ml ($p = 0.003$) respective 1.053 ng/ml ($p = 0.049$) in LC and 2.02 ng/ml in blood ($p < 0.0001$) and 9.39 ng/ml in urine ($p = 0.003$) in patients with HCC. There is a perfect correlation between serum and urinary levels of STC in controls ($r = 1$), that become weak in patients with LC ($r = 0.48$) and insignificant in HCC ($r = 0.15$). AFP values were significantly correlated with STC concentration in patient with HCC, in both blood ($r = 0.31$) and urine ($r = 0.84$). **Conclusions:** STC values in patients with LC and HCC were significantly higher compared to controls. Strong positive correlation of STC with AFP in patients with liver cancer suggested a possible role of this mycotoxin in pathogenesis of the disease. **Key words:** MYCOTOXIN, STERIGMATOCYSTIN, LIVER CIRRHOSIS, HEPATOCELLULAR CARCINOMA, ALFA-FETOPROTEIN

Micotoxinele sunt substanţe naturale care apar ca produşi secundari de metabolism ai fungilor filamentoşi care contaminează hrana animalelor şi oamenilor. Contaminarea cu micotoxine este considerată inerentă (1,2), eforturile depuse urmărind limitarea acesteia la niveluri considerate sigure pentru sănătatea oamenilor şi animalelor.

Clasele majore de micotoxine includ: aflatoxinele, tricotecenele, fumonizinele, zearalenone, ocratoxinele şi alcaloizii de ergot (1), majoritatea acestora fiind produse de fungi din genurile *Aspergillus*, *Penicillium* şi *Fusarium*. Principala micotoxină, atât din punct de vedere al cantităţilor produse, cât şi din punct de vedere al efectelor biologice (substanţa naturală cu cel mai puternic efect

TABELUL I
Valorile STC determinate la cele trei loturi de studiu

Lot	Număr probe pozitive		Procent probe pozitive		Valoarea maximă[a]		*p*[b]	
	Sânge	Urină	Sânge	Urină	Sânge	Urină	Sânge	Urină
Martor	2	2	3.63	3.63	0.38	0.13	-	-
CH	22	16	37.93	27.58	11.80	39.06	<0.0001	<0.0001
CHC	28	17	52.83	32.87	2.02	9.39	0.0005	<0.0001

a – ppm (părţi per milion) sau ng/ml ; b – test t-Student, comparativ cu lotul martor

TABELUL II
Valoarea AFP şi corelaţia cu STC

Lot	AFP	p[a]	Coeficient de corelaţie[b]	
			Sânge	Urină
Martor	4,42	-	0.004	0.004
CH	12,63	0.004	-0.02	0.05
CHC	1252,79	0.0002	0.31	0.84

a – testul t-Student ; b – coeficient de corelaţie (test Pearson)

carcinogen) este aflatoxina B_1 (AFB_1) (1,2).

Sterigmatocistina (STC) este o aflatoxină produsă de genul *Aspergillus* (*A. versicolor* – principalul producător de STC ; *A. nidulans*, *A. chevalieri, A. ruber*), şi de unele tulpini de *Penicillium, Bipolaris, Chaetomium, Emiricella* (1,2,3). Din punct de vedere chimic, STC este un precursor al AFB1, în care se poate transforma atât *in vitro* cât şi *in vivo* printr-o singură reacţie (1,2), producând aceleaşi efecte biologice.

Metabolizarea STC este predominant hepatică, rolul esenţial avându-l complexul CYP3A4, pentru care are o mare afinitate . Activarea STC este dependentă de enzimele citocromului P450, metabolizarea fiind iniţiată la nivelul dublei legături C_2-C_3 (1). Rezultatul este STC-2,3-epoxidul, care este instabil în mediul apos şi este rapid hidrolizat neenzimatic la dihidrodioli. Toţi aceşti compuşi au capacitatea de a forma adducţi cu ADN, acţionând la nivelul 7N al guaninei (1), similar cu AFB_1. STC este creditată cu 10% din capacitatea carcinogenetică a AFB_1 (3) şi declarat carcinogen de ordinul II (3), dar pare să fie mai toxică decât aceasta pentru rinichi (12).

OBIECTIVE

Studiul a urmărit detectarea prezenţei STC în sângele şi urina pacienţilor cu boală hepatică avansată, precum şi stabilirea corelaţiilor acesteia cu parametrii funcţiei hepatice.

MATERIAL ŞI METODĂ

Pacienţi. În studiu au intrat 166 de pacienţi divizaţi în : lot martor – 55 pacienţi (27M, 28F), fără afectare hepatică ; ciroză hepatică (CH) – 58 de pacienţi (31M, 27F) ; carcinom hepatocelular (CHC) – 53 de pacienţi (26M, 27F). Vârsta medie a participanţilor a fost de $57,9 \pm 8,4$ ani în lotul martor, $57,2 \pm 10,3$ ani în lotul cu CH ($p=0.33$) şi $63,7 \pm 10,2$ ani în lotul cu CHC ($p=0.001$ faţă de martor, $p=0.0006$ faţă de CH). Structura loturilor şi distribuţia pe medii de provenienţă este redată în Fig. 1. De la toţi pacienţii au fost recoltate în prima zi de la internare 20 ml de sânge periferic pe EDTA şi 50 ml de urină.

Teste biochimice. Folosind metoda chimiei umede (Hitachi), au fost determinate enzimele de citoliză hepatică (TGP, TGO) şi de colestază (FA, GGT). α-fetoproteina serică (AFP) a fost determinată prin electroche-

miluminiscenţă, pe aparat Modular E 170.

Cromatografia de lichide de înaltă performanţă (HPLC). Detecţia STC în probele analizate s-a făcut utilizând metoda HPLC. S-a folosit un cromatograf de lichide tip HP 1090 cu detecţie simultană în UV la 251 nm şi în fluorescenţă (excitaţie la 228 nm şi emisie la 423 nm) prevăzut cu o coloană C18 tip Zorbax (15 cm x 4,5 mm, 5 μm), cu o fază mobilă formată din amestec acetonitril : metanol : apă (99 : 99 : 2) la un debit de 0,7 ml/min, conform metodei descrise anterior (16), după precipitarea proteinelor din sânge cu acetonitril, purificare cu izooctan, extracţie cu cloroform şi reluarea reziduului obţinut, după evaporarea la sec, cu metanol. Folosind ecuaţia curbei de calibrare obţinută la studiul liniarităţii din cadrul validării metodei de analiză, utilizând soluţii de AFB1 şi STC în concentraţii cunoscute, s-a calculat concentraţia în micotoxine din probele de sânge recoltate de la pacienţi. Precizia metodei (RSD) este de 16,9629% cu o regăsire medie de 99,2%.

Analiza statistică. Rezultatele obţinute au fost incluse într-o bază de date Microsoft Excel 2010. Prelucrarea statistică s-a făcut folosind testul Fisher, testul *t-Student* şi testul de corelaţie Pearson, iar valoarea $p < 0.05$ a fost considerată semnificativă statistic.

REZULTATE ŞI DISCUŢII

Din totalul de 332 probe analizate, un număr de 87 de probe (26,2%) au prezentat nivele detectabile de STC, cele mai multe în lotul cu CHC (tab. I). Ambele loturi de pacienţi cu afectare hepatică au fost depistaţi pozitiv mai frecvent decât martorul, dar nu există diferenţe statistic semnificative între frecvenţa înregistrării probelor pozitive la pacienţii cu hepatocarcinom faţă de cei cu ciroză, atât în sânge ($p = 0.17$), cât şi în urină ($p = 0.68$). Recoltarea de sânge şi urină a fost efectuată în prima zi de internare, astfel încât valorile determinate reflectă gradul de ingestie al micotoxinei în alimentaţia obişnuită, de la domiciliu, a pacientului.

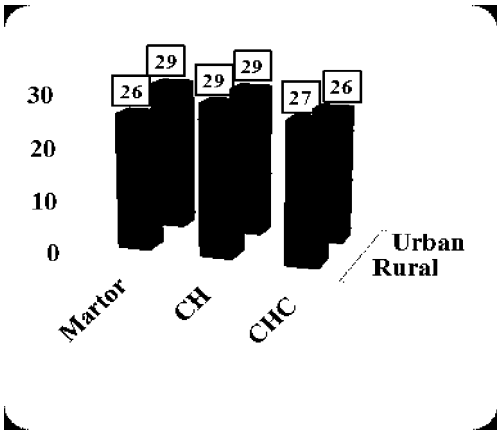

Fig. 1. Structura loturilor de studiu

Valorile medii ale concentraţiei STC în sângele şi urina lotului martor au fost de 0,014 ng/ml, respectiv de 0,005 ng/ml, fiind semnificativ statistic mai mari la pacienţii cu CH : 0,626 ng/ml în sânge ($p = 0.003$) şi 1,053 ng/ml în urina ($p = 0.049$). Concentraţia STC în probele recoltate de la pacienţii cu CHC a fost semnificativ mai mare decât a lotului martor, atât în sânge ($p < 0.0001$) cât şi în urină ($p = 0.003$), dar fără diferenţe statistic semnificative faţă de rezultatele înregistrate în lotul cu CH ($p = 0.17$, respectiv $p = 0.44$). Există o corelaţie perfectă între valorile serice şi urinare de STC la lotul martor ($r = 1$). Aceasta este semnificativă, dar mai slabă, pentru lotul cu CH ($r = 0.48$), şi se pierde la lotul cu CHC ($r = 0.15$).

Existenţa corelaţiei între valorile serice şi urinare ale STC la lotul fără afectare hepatică semnifică paralelismul între aportul şi eliminarea toxinei. Pierderea acestei corelaţii la loturile cu afectare hepatică avansată reprezintă probabil efectul perturbator pe care afectarea capacităţii de metabolizare hepatică îl are asupra biotransformării STC. Cum la pacienţii cu CH şi CHC numărul de probe pozitive este mai mare în sânge decât în urină, la aceste loturi capacitatea de metabolizare a STC să scadă, prelungind astfel acţiunile biologice ale acesteia.

Nu există diferenţe statistic semnificative între pacienţii provenind din medii diferite, nici între bărbaţi şi femei, pentru nici unul din loturile studiate.

Nu s-au înregistrat diferenţe statistic semnificative între valorile transaminazelor determinate în cele trei loturi. Valorile enzimelor de colestază au fost mai mari în lotul cu CH şi CHC, faţă de martor, dar fără să existe diferenţe semnificative între pacienţii cu boală hepatică cronică. Nu există corelaţii semnificative între valorile enzimelor de citoliză hepatică sau colestază şi concentraţiile de STC, pentru nici unul din cele trei loturi. Acest fapt sugerează că diferenţele sunt determinate de procesul fiziopatologic hepatic, fără a fi implicată ingestia de micotoxine.

Valorile AFP au fost maxime la pacienţii cu hepatom, diferenţele faţă de martor şi cirotici fiind înalt semnificative statistic (tab. II). La loturile martor şi cu CH, nu există o corelaţie între valoarea AFP (marker biologic al procesului de carcinogeneză hepatică) şi STC. La lotul cu CHC, această corelaţie este prezentă şi pozitivă, mai ales în cazul valorilor STC urinare, unde este foarte puternică ($r = 0.84$). Acest fapt sugerează existenţa unei corespondenţe între gradul intoxicaţiei cu STC şi procesul carcinogenetic hepatic, mai ales în contextul în care activitatea mutagenică a acesteia a fost dovedită experimental (17,18). Valorile mari ale STC urinare corespund unei detoxifieri hepatice mult scăzute. Ele pot semnifica rolul important al intoxicaţiei în procesul patogenia hepatomului la aceşti pacienţi, sau pot reprezenta consecinţa scăderii pronunţate a capacităţii ficatului de a metaboliza STC, astfel încât acesta este eliminată sub formă parentală.

CONCLUZII

Se remarcă în mod evident niveluri mai ridicate ale concentraţiei de micotoxină la pacienţii cu boli hepatice avansate în comparaţie cu lotul martor, ceea ce susţine rolul STC în afectarea hepatică şi mai ales în producerea cancerului hepatic. Creşterea semnificativă a valorilor STC urinare la pacienţii cu hepatocarcinom poate reprezenta atât cauza, cât şi efectul procesul carcinogenetic hepatic.

CARDIOVASCULAR RECOVERY IN ELDERLY PATIENTS (Abstract): Cardiac rehabilitation of elderly patients is becoming a growing necessity because, with aging, the prevalence of cardiovascular disease increases. The most vulnerable population, the elderly, might have greater needs for cardiac rehabilitation because the likelihood of being fragile is very high. After hospitalization for such an event as acute coronary syndrome or cardiac decompensation, all patients, but especially the elderly, are at increased risk for destabilization, being eligible for new cardiovascular events that may have a disabling impact on both physical and mental health. The efficacy and safety of cardiac rehabilitation has been also demonstrated in elderly patients with stable coronary artery disease, in those who underwent coronary intervention or in patients with chronic heart failure. Cardiac rehabilitation programs are designed to enhance recovery after an acute cardiovascular event and improve both quality of life and survival by measuring secondary prevention - controlling risk factors, physical activity, diet and optimizing medical treatment. Over the years, all the evidence has shown comparable benefits in elderly and younger patients. Particular attention should also be paid to frail elderly patients who need a personalized intervention. Frailty is defined as a complex of biological markers and clinical characteristics seen in a dynamic position between a healthy status and extremely severe clinical status. Frailty puts many elderly patients at greater risk of health destabilization and first it is necessary to prevent and to treat not only in an "acute" care setting, but also a "post-acute" recovery through home care. **Keywords:** CARDIOVASCULAR RECOVERY, CARDIOVASCULAR PATHOLOGY, CARDIAC DECOMPENSATION, FRAILTY, QUALITY OF LIFE, ELDERLY.

Cardiac Rehabilitation (CR) is defined World Health Organization (1) as a complex medical program primarily offered to patients with severe cardiovascular disease (acute myocardial infarction, heart failure, transluminal angioplasty, cardiac surgery) and aimed at improving cardiac function with the help of individually dosed exercise, lifestyle change with improvement of cardiovascular risk factors (diabetes mellitus, hypertension, smoking, obesity, dyslipidemias) and, last but not least, at managing daily life stress and stress induced by ongoing cardiac disease.

CR is represented by a multitude of comprehensive long-term programs that include medical assessment, physical activity prescription, changing risk factors, edu-

cation, and medical advice. These programs aim at limiting the physiological and psychological effects of heart disease, reducing the risk of sudden death and reinfarction, controlling cardiac symptoms, regression or stabilization of atherosclerosis, and improving the psychosocial and occupational status of patients. In the past, CR was indicated to young patients to facilitate their reintegration into society as soon as possible, to resume activities after surgery or after a stroke.

Cardiovascular disease is estimated to cause over 4 million deaths each year in Europe, with over 1.9 million cases in the European Union countries, thus placing cardiovascular disease as the leading cause of death (2).

Over the past 30 years we have witnessed a world population aging, with dramatic effects on the demand for medical services, with the highest increases for cardiovascular diseases. On January 1st, 2017 the population of Romania was 22.22 million people. The population aging phenomenon has intensified, the elderly population (65 years old and over) exceeding by 269,000 the young population aged 0-14 (3.55 million elderly versus 3.28 million young people). The demographic aging index has increased from 105, 8 (January 1st, 2016) to 108.2 elderly per 100 young people (January 1st, 2017) (3).

The mean age of the population was 41.1 years, 0.2 years higher than on January 1st, 2016. The median age was 40.8 years, up 0.4 years from January 1st, 2016.

Cardiovascular diseases remain the leading cause of death among elderly worldwide with combined prevalence rates of >50% of the following conditions: heart failure, cardiac arrhythmias, stroke, and peripheral vascular disease (4).

In Romania, among elderly people aged 65 and over compared to people aged 15-64, morbidity rate is double, with cardiovascular diseases being almost 4 times more common, followed by diseases of the nervous system, osteoarticular system, degenerative muscular disorders, neoplasms, mental and behavioral disorders. In addition, the almost universal risk of developing high blood pressure during life, coupled with the increasing rate of multiple cardiovascular risk factors, contributes dramatically to the increased incidence and prevalence of cardiovascular diseases with age (5).

This in the context of age-related normative changes in cardiovascular structure and function, which result in a phenotype that predisposes older people to cardiovascular disorders and amplifies their sequels. Consequently, although mainstream cardiology becomes de facto geriatric cardiology, in many places older adults with cardiovascular disease are often not cared for by cardiologists or geriatricians, but rather by primary care providers and allied medical professions.

Under these conditions, CR in the elderly patient becomes an imperative necessity, even more so since the studies conducted over the past 20 years show that physical training in rehabilitation programs for the elderly has similar effects to those achieved in the adult. Studies in elderly patients with coronary artery disease and/or heart failure show that CR offers similar benefits to younger subjects through physical rehabilitation, increased functional capacity, and reduced cardiovascular risk. Research has shown that there may be even greater increases in aerobic capacity following a personalized physical exercise program in this age category (6).

Starting an CVR program in the elderly patient will need to consider a number of peculiarities encountered at this age:

- occurrence/increase/worsening of frailty, manifested by: decrease in muscle mass (sarcopenia), nutrition disorders, progressive worsening of osteoporosis, increased risk of falling (7, 8);

- concomitant presence of other diseases than the existing cardiovascular ones might have a significantly impact on CR: osteoarticular, neurological, respiratory, ophthalmic diseases;

- occurrence of cognitive disorders, depression and delusional episodes - caused by inexorable changes in the emotional, social and emotional life of the elderly and aggravated by the presence of cardiovascular and concomitant diseases.

Before initiating a CR program, it must be considered that the diseases of the elderly patients are chronic, long-lasting, requiring high consumption of medical services (consultations, medical treatments, repeated and long-term hospitalizations) and permanent medical-social care, domestic and personal hygiene, institutionalization). Loneliness, impairment of sexual activity and chronic metabolic disorders are some of the causes that can lead to emotional disturbances and decreased quality of life I the elderly (9, 10) (fig. 1).

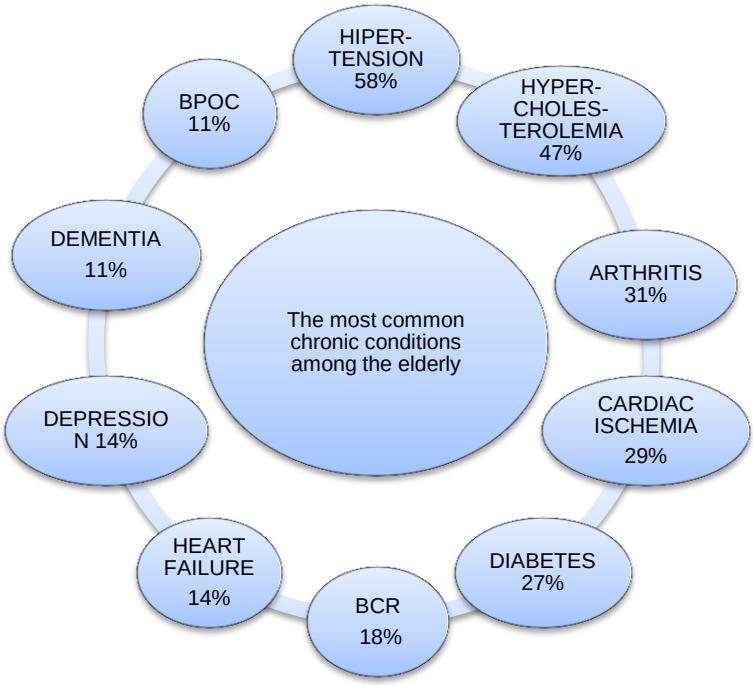

Fig. 1. The most common chronic conditions among the elderly

Elderly people need to be encouraged and helped to live healthy, productive, participative, dignified and independent lives, and in this respect three major general objectives must be met: prolonging active life, promoting social and welfare

participation for the elderly, and achieving more independence and safety for people in need for long-term care.

Farzianpour *et al*. (9) concluded in one of their studies that the elderly who have an active lifestyle automatically have a better quality of life, are less depressed, more satisfied and more socially active. Older people who can carry out their daily activities are also less likely to become depressed, and thus the decompensation rate is lower. Similar results are reported by Prescott *et al*. (11) who support that many patients with cardiovascular impairment, physical, social limitations, and unstable health, become anxious or depressed as the state of incapacity and frailty is prolonged.

The goal of the CR is to help the elderly to regain their physical form before the disease, to prevent physical deconditioning and subsequent vascular accidents. CR provides the opportunity to fight predictable geriatric complications in elderly patients with cardiovascular disease (CVD), including:

1) co-morbidity (multiple cardiac and non-cardiac diseases occurring in combination);

2) polymedication (multiple new drugs in the context of age-related changes in pharmacokinetics and pharmacodynamics predisposing to undesirable side effects),

3) iatrogenic processes (harmful effects of polypragmasy, repeated and prolonged hospitalizations and transitions including delirium, deconditioning, further institutionalization, and occurrence and/or worsening of sarcopenia and poor quality of life) (12).

CR is one of the few standard therapeutic options that aims to improve physical function as a primary outcome and which therefore has the potential to improve prognosis of heart disease but also to reduce age-related vulnerabilities such as frailty and disability, and which are usually exacerbated by CVD.

The study by Harada *et al.*, (13) suggests that the CR, together with good nutrition control, risk prevention and drug treatment, can be a useful strategy for the prevention and treatment of sarcopenia in patients with CVD.

Recovery in cardiovascular disease is not only a physical exercise program but also a lifestyle education and change program designed specifically to increase the quality of life of the elderly patient with cardiovascular pathology (myocardial infarction, after surgery for CVD, arterial, and peripheral venous disease). Finally, rehabilitation programs have the role of increasing the chance of survival of patients.

Attention should be paid to increasing the quality of life of the elderly patient to the level of his/her expectations. The quality of life of patients with CVD is significantly affected, especially in the elderly, due to several factors, including the high risk of recurrence of cardiovascular events, admission to hospital, physical disability, co-morbidity and general frailty. With physical and social limitations and unstable health, many patients become anxious or depressed.

In a recent study, Vigorito *et al*. (14) warn that the prevalence, clinical and prognostic relevance of frailty in a cardiac rehabilitation setting has not yet been well characterized, although many studies have reported frailty in patients with coronary syndromes in intensive care or cardiology units. At the same time, frailty complicates the recovery and treatment of elderly patients as it can affect the type and timing of

diagnostic procedures and pharmacological and non-pharmacological treatment (5). The assessment of the basic physical function must be adapted to physical conditions and the CR program must be individualized based on functional compromise and disability (tab. I).

TABLE I
Indications of cardiovascular recovery

INDICATIONS OF CARDIOVASCULAR RECOVERY		
CLASS I	CLASS II	CLASS III
Certain indications for rehabilitation	Possible indications with probable but still controversial effectiveness	Contraindications or non-indications for rehabilitation

Cardiovascular damage is a major cause of disability and decreased quality of life, regular physical activity under the guidance of professionals representing the main non-medical factor - and thus without adverse effects - that can effectively help in the secondary and tertiary prevention of this pathology (15).

Currently, due to improved programs and medical monitoring, CR has become accessible to people of any age who have cardiovascular disease. Menezes *et al*. (16, 17) claim that, as the population ages, a growing proportion of inactive adults, aged at least 85, will be candidates for the CR. Specific care processes (both in terms of physical exercise and wider goals of CR) will need to be better suited to the needs of an increasing population of vulnerable elderly people.

Exercise has beneficial effects on physical state and on cardiovascular risk factors. Physical endurance training increases exercise capacity and more effectively influences the risk factors for ischemic heart disease. It reduces the percentage of fat in the tissues and reduces the risk of obesity, increases bone mineral density, thus reducing the risk of osteoporosis, the risk of falls and fractures, decreases insulin response to glucose loading and prevents diabetes, lowers serum lipids, increases HDL cholesterol, reduces dyslipidemia and atherogenic risk, lowers heart rate and blood pressure, improves cardiac output and cardiac performance, improves basal metabolism, improves sleep quality, increases quality of life, reduces mortality in post-myocardial infarction patients, relieves symptoms in patients with angina pectoris, increases exercise capacity, quality of life improves mental health and mood and decreases depression rate, reduces hospital readmission rate and increases survival. In cardiac failure, physical training increases exercise capacity (VO_2 max), improves cardiac output, increases the size and density of mitochondria, improves skeletal muscle metabolism and function, reduces endothelial dysfunction, and lowers plasma catecholamine levels; in patients with lower limb arteriopathy obliterans, exercise is very effective, helping to increase the walking distance and maximally tolerated pain in elderly patients (18, 19) (fig. 2).

To support the above statements, Schopfer *et al*. (12) concluded in a review-

type study that CR is more than a program, but a complete lifestyle that can have a benefit for elderly patients with CVD and that the maintenance of physical function (cardiorespiratory fitness, as well as strength and balance) helps to overcome progressive disease and deconditioning as well as associated vulnerabilities.

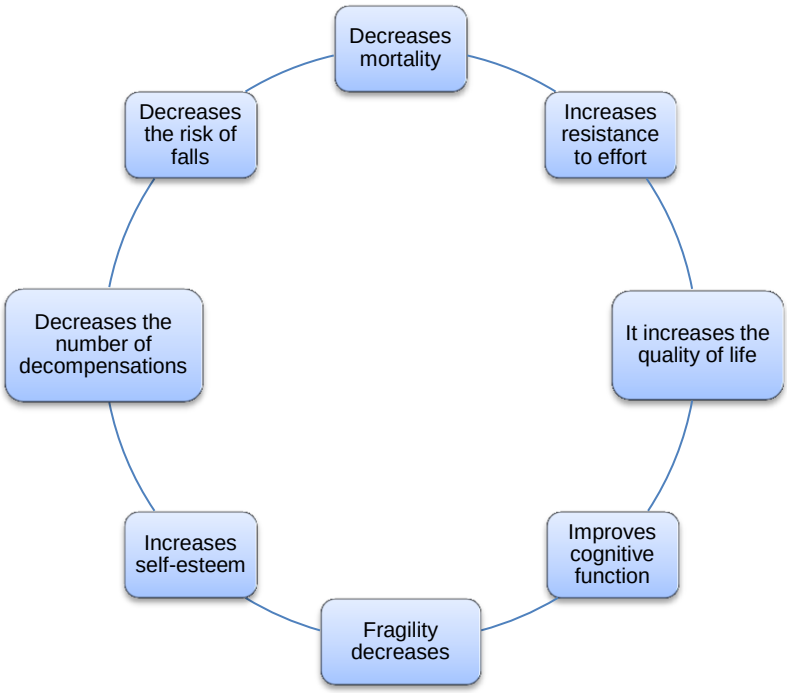

Fig. 2. Benefits of cardiovascular recovery in elderly patients

Baldasseroni *et al*. (19) also concluded in their study, which enrolled patients aged 75 years and older who presented themselves to an outpatient treatment unit following an acute coronary event (unstable angina, acute myocardial infarction) or heart surgery (coronary bypass), that a CR program based on physical exercise was associated with the improvement of all areas of physical fitness even in older adults, especially those who had lower baseline performance.

Nishant *et al*. (20) believe that in the present state of knowledge additional investigations are needed to better understand the impact of CR on heart failure and that recent literature presents its benefits in these patients, although much of the evidence is limited to patients with systolic dysfunction; also, it encourages the exploration of strategies to increase the use of CR.

CONCLUSIONS

In our opinion, based on the researches made, the rehabilitation process for the elderly should be implemented in accordance with the exercise-related risk assessment criteria and adapted to the different disease-related patterns and disabilities.

Disability tends to coincide with a state of complexity, comprising a broad spectrum of cardiovascular and non-cardiovascular diseases associated with underlying cardiac disease characterized by varying degrees of impairment of functional capacity. This comes from a disability that causes varying degrees of frailty, thus limiting the individual's participation in social life.

Therefore, rehabilitation intervention can be guided by a multidimensional assessment configured in patients with moderate cardiovascular disease in a classical physical training program, while patients with severe cardiovascular disease and more limited functions may be subjected to physical activity that, even if not an effective stimulus for training, helps prevent total disability. In any case, CR configures an operational framework that involves different reasons from many professions, depending on the degree of disability and the different patient needs. The process of rehabilitation of these patients will be strictly individualized in relation to their functional impairment/admission disability and normal functional capacity. The proposed Protocols do not follow the traditional approach to rehabilitation in cardiology (different protocols for different events or acute or chronic illnesses) but instead propose a cross-sectional criterion for different clinical scenarios based on different levels of patient disability.

NEWS

BRONCHIAL HYPER-RESPONSIVENESS: A TEHNICAL UPDATE

Bronchial hyper-responsiveness (BHR) is often regarded as a "hallmark" of asthma, and bronchoprovocation testing is frequently performed to support a diagnosis of asthma. The European Respiratory Society (ERS) and American Thoracic Society (ATS) have recently updated their technical standards and guidelines for performing methacholine challenge testing (MCT), the most commonly performed clinical test of BHR. The new guidelines recommend that methacholine challenge testing be performed using tidal breathing, not deep inspirations with breath holding. Results should be reported as the PD20 (cumulative dose causing a 20% fall in forced expiratory volume in 1 s), rather than PC20 (concentration causing a 20% fall in forced expiratory volume in 1 s). Manufacturers of nebulizes and other delivery systems should provide performance characteristics to allow calculation of PD20 values. The clinicians who utilize and evaluate BHR testing are encouraged to understand the differences among various MCT protocols. Of particular importance is an appreciation of the relatively high likelihood of false negative tests in mild or asymptomatic asthmatics, and the difficulty of interpreting MCT over time when testing methods are not held constant. Finally, there is hope that clinicians will encourage their hospitals and pulmonary function laboratories services to more actively adopt the recent guidelines (Borak J, Lefkowitz RY, Linde B. Bronchial hyper-responsiveness: a technical update. *Occupational Medicine* 2018, kqy122, https://doi.org/10.1093/occmed/kqy122).

3. Department of Genetics

HEREDITARY HEMOCHROMATOSIS IN NORH-EASTERN ROMANIA (Abstract): Hereditary hemochromatosis is a genetic disturbance of iron metabolism resulting in iron overload in several organs and their functional failure. Early diagnosis is necessary to start a simple and effective therapy: bleeding. It is the most frequent genetic disease in some populations. Our **objectives** were 1. An estimate of the expectancy of the disease in the population of our geographic region, and 2. To diagnose the disease by applying the established methods and estimate the efficiency of our diagnosis. **Methods**: 1.To estimate the expectancy, we genotyped 200 persons for the most frequent mutations causing the disease: HFE-C282Y and HFE-H63D by PCR-RFLP. 2. To diagnose the disease phenotypically we determined plasma iron level, ferritin level and transferrin saturation index in 549 patients previonsly diagnosed as chronic hepatitis or cirrhosis and genotyped those with hemochromatosis phenotype. **Results**: 1. We found allelic frequencies of 1.75% and 13.25% for the HFE-C282Y and H63D mutant alleles respectively. From these frequencies we calculated that a severe case caused by a C282Y/C282Y homozygote can arise in 816 people and a mild case caused by a C282Y/H63D compound heterozygote can arise in 100 people 2. Among 549 patients we found 10 to have the phenotype of hemochromatosis and 3 out of the 10 were found to carry mutations: two in the HFE gene (one homozygous C282Y and one compound heterozygous C282Y/ H63D) and one in the hemojuvelin (HJV) gene (a G320V). **Key words**: PREVALENCE, HFE-C282Y, HFE-H63D, HJV-G320V

Hereditary hemochromatosis is the most frequent genetic disease in some regions of Europe such as Scandinavia, Ireland, Britain (UK) and Brittany (France). In these regions the disease is a public health problem. In other European and American regions its frequency is lower but its severe consequences and its curability makes early diagnosis very important. This is also our reason for initiating its study in our region. Some of our results have been published elsewhere (1) or are being prepared to be published. This is a summing-up report of what we have done to date.

The disease has been described by Trousseau in 1865 as 'bronze diabetes with cirrhosis' and coined as hemochromatosis by Recklinghausen in 1889. In 1996 the HFE gene and its mutations C282Y (a cysteine to tyrosine substitution at codon 282) and H63D (a histidine to aspartic acid substitution at codon 63), were described by Feder and colleagues (2). About 83% of patients genotyped by Feder were C282Y homozygous. Since the HFE gene discovery, new genes have been discovered to be involved in hemochromatosis and their encoded proteins to be involved in iron metabolism.

Brief presentation of iron-overload pathophysiology. Hemochromatosis is due to iron overload in tissues, resulting in death of cells. The outcome of iron overload can be hepatic cirrhosis, heart failure, diabetes, arthroses, hypogonadotropic hypogonadism etc. Iron overload is due to a systemic deregulation of iron metabolism. The central regulator of iron homeostasis is hepcidin, a polypeptide of 25 aminoacids secreted by hepatocytes into plasma (as a hormone). Almost all iron overloads are dues to a hepcidin deficiency, except one caused by the ferroportin excess. Ferroportin is a protein expressed by enterocytes, hepatocytes and macrophages and is inserted into those cells membranes where it facilitates iron export. The ferroportin expression is negatively regulated by hepcidin. Extracellular hepcidin binds membrane ferroportin causing its internalization and proteolysis (3).

Hepcidin's expression and secretion by hepatocytes is upregulated by several proteins organized into at least two pathways. One pathway is acted by Fe-transferrin (Fe-Tf), transferrin receptor 1 (TfR1), transferrin receptor 2 (TfR2), and HFE. HFE, a protein of the major histocompatibility complex I (MHC) superfamily, can form complexes with both TfR1 and TfR2 transferrin receptors, but in different manners. Association of TfR1 with Fe-TF or HFE is mutually exclusive (i.e. TfR1 associates with either HFE or Fe-Tf), while TfR2 associates with both Tf and HFE. The ternary complex TfR2-Tf-HFE is the positive transcription regulator of the HAMP gene encoding hepcidin's precursor. Fe-Tf abundance in plasma releases HFE from TfR1 in hepatocytes, making it available for the ternary complex TfR2-Tf-HFE which increases the hepcidin synthesis and secretion. Hepcidin negatively regulates ferroportin activity and a retention of iron in enterocytes and macrophages (main sources of plasma iron) occurs, maintaining a constancy of plasma iron–transferrin concentration (4).

A second pathway regulating the hepcidin level is acted by hemojuvelin and the members of the bone morphogenetic proteins (BMP) signaling pathway. This pathway assures an influence of infection/inflammation and hypoxia over the iron metabolism via hepcidin secretion (4). Hemojuvelin deficiency is associated with a very severe iron overload.

Type 1 of hereditary hemochromatosis is due to mutants inactivating HFE. Type 2A, 2B and type 3 hemochromatosis are dues to inactivating mutations in hemojuvelin, hepcidin and transferrin receptor 2 (TfR2) respectively. Type 4 hemochromatosis is due to mutations in the ferroportin encoding gene that preclude ferroportin to be negatively regulated by hepcidin.

Our approach to hemochromatosis in our geographical region. We had two objectives in our study : 1) To estimate the expectancy of the disease by genotyping a sample of normal population for the most frequent HFE mutations, C282Y and H63D, and 2) To use and optimize methods of discovering the disease among patients.

MATERIALS AND METHODS

Population samples : For the prevalence of the C282Y and H63D alleles in the healthy population the sample consisted of 200 individuals. Forty were healthy blood donors and 160 were ambulatory and hospitalized patients with diagnoses not suggesting hemochromatosis, liver diseases, diabetes or rheumatism. We included these patients in the sample in order to vary its geographical origin. Eighty -five originated from the Iasi district (including the blood donors), 33, 19, 23, 24 and 16 individuals originated from the districts of Vaslui, Bacau, Botosani, Suceava and Neamt respectively. 105 were males and 95 were females. All the subjects were genotyped for C282Y and 146 subjects were genotyped for H63D.

TABLE I
Mutant genotypes of HFE and their frequency in Moldavia

Genotype	Nr of subjects tested	Nr of subjects with genotype	Percentage
C282Y/+	200	7	3.5
C282Y/ C282Y	200	0	0
H63D/+	140	28	20
H63D/H63D	140	4	2.9
C282Y/ H63D	140	0	0

For searching the disease among patients, the sample consisted of 549 patients hospitalized at the Institute of Gantroenterology and Hepatology Iaşi, diagnosed as chronic hepatitis or cirrhosis. The ages were : under 30 : 28 patients ; 30-39 : 79 patients ; 40--49 : 177 patients ; 50-59 : 235 patients ; over 60 : 30 patients ; 208 were men and 241 were women. The patients were tested for plasma iron level, transferrin saturation index, and ferritin level in addition to other investigations (including liver biopsies in some cases) specific to their pathology. Ten patients having high cumulated levels of blood iron, transferrin saturation index and ferritin or a hepatic iron overload, discovered at the liver biopsy were genotyped for C282Y and H63D and one of them was sequenced for mutations in ferroportin, hepcidine and hemojuveline genes. Informed consent was obtained from all the subjects in the two groups mentioned.

Biochemical investigations : Iron level and the total capacity of iron binding were determined colorimetrically by using commercial kits. Transferrin saturation index was calculated from the two values aforementioned. Ferritin was determined by using an immunochemical method with a commercial kit.

Genotyping : The C282Y and H63D mutations were tested by a PCR- RFLP analysis as described (1,5). Parts of the HFE gene were PCR amplified using appropriate primers and the amplicons obtained were digested with restriction enzymes : RsaI for C282Y and MboI for H63D. The fragments obtained were analyzed for their sizes after electrophoretic separation in agarose gels.

The sequencing of ferroportin, hepcidin and hemojuvelin genes was carried out in the molecular biology laboratory of the Lille University Hospital (France) by one of us.The genomic DNA was extracted with a Qiagen kit, The entire coding regions and splice sites of all these genes were sequenced using a terminator cycle sequencing reaction kit and a 3130 XL Genetic Analyzer (Applied Biosystems),

RESULTS

Our first goal was to evaluate how frequently we expect a hemochromatosis case in our population. A population sample of 200 persons from the Moldavian territory was organized, consisting of individuals not suspected of hemochromatosis. The distribution of HFE mutant alleles in our population group designed to evaluate prevalence of mutations in HFE gene are presented in Table I.

The allele frequency (nr. of chromosomes carrying the mutant allele x 100 / total nr of chromosomes) calculated from the data (tab. I) are 1.75 (95% confidence interval : 0.7 – 3.7) for the C282Y mutant allele and 13.25 (95% confidence interval 10.4 – 16.5) for the H63D allele. Also from the data, there is an expectancy of one homozygous (possibly ill) C282Y/C282Y person out of 816 persons. This would be so if penetrance of the mutant allele was 1. However, penetrance is lower than 1 and varies in different populations (6). As we do not know yet penetrance (nr of persons with phenotype / nr of persons with genotype) in our population, we can only assess that we expect at most one person suffering from hemochromatosis among 816 persons. As to the compound heterozygote C282Y/H63D its expectancy

is much higher (one out of 100 individuals), but this genotype very rarely causes hemochromatosis (generally a mild iron overload with little clinical consequences) (6).

Our second goal was to apply and optimize a selection method in order to discover among clinically suspects the persons who really suffered from hemochromatosis. As genotyping is more expensive and do not always discover the disease, we tested 549 patients, whose clinical status suggested possible hemochromatosis for iron-overload parameters generally recommended (6): plasma iron level, transferrin saturation index and ferritine level. We selected eventually 10 patients cumulating iron blood levels higher than 160 mg/dL, transferrin saturation index higher than 70 and a ferritin level higher than 500 ng/mL for genotyping. Three of them were found to carry mutations: one was a HFE C282Y/C282Y homozygote, another one was a HFE C282Y/H63D compound heterozygote and the third one had no mutations in HFE. After sequencing other genes (ferroportin, hepcidin and hemojuvelin genes) a homozygous G320V mutation was finally found in the hemojuvelin gene.

DISCUSSION

In this study we aimed to diagnose hemochromatosis among our patients. First we wished to estimate the status of the most frequent mutations causing hereditary hemochromatosis, the HFE C282Y and H63D mutant alleles, in the broad population of our region. We established a population sample of 200 people from most part of the districts of the region. Subjects composing the sample were healthy blood donors and (in majority) patients with various diseases, but not the ones possibly suggesting hemochromatosis. We think that did not cause a bias of the data since the mutations we found were in heterozygous condition, known as not having a phenotype. The allelic frequency of the HFE- C282Y found in our population, 1.75%, can be compared with allelic frequencies in other regions in Eastern Europe: northwestern Poland 4.73% (9), southern Poland 3.11 % (10) , Moscow region 3.4 % (11), Czech Republic 3.45 % (12), Hungary 3.40 % (13), Slovenia 3.61 % (7), Croatia 3.30 % (8) , Serbia-Montenegro 1.60 %(14), Bosnia-Herzegovina 2.25 % (15) Bulgaria (Sofia Region) 0 % (16), Greece 0.3 % (17). Our figure fits approximately the interesting (but not very well understood) pattern of northwest-to-southeast decline of the frequency available in Europe. This may account for the population migrations in the past. The allelic frequency of H63D in our population (13.25) is close to the frequencies in almost all European and non European populations.

From our figures a maximal expectancy of one individual affected by severe hemochromatosis in approximately 800 people can be calculated, which makes hemochromatosis still a rare disease, but the most frequent genetic disease in our region and justifies special attention from the medical services.

We also tested a practical method to discover hemochromatosis in patients who, we had reasons to suspect, were suffering from it. We applied the established rules as to discover the phenotype (6) and we found 10 patients having a hemochromatosis phenotype in a sample of 549 patients. They were genotyped for the HFE mutations and one of them was a C282Y/C282Y homozygote. This was close to expectancy in the general population, although we expected more in a group of pathology selected patients. This could be due to the lower than 1 penetrance of the mutant allele as well as to flaws in the phenotype or genotype determination, resulting in missing of some cases. A similar evaluation in a group of patients from southwestern Romania, four C282Y homozygotes were found among 21 cases of iron overload (18). As to the other

7 cases of phenotypic hemochromatosis in our group, some may have been secondary hemochromatosis (one of them had a myelodysplasic syndrome) and others may have had mutations in other genes. This was proved in one of them by sequencing other genes and finding a homozygous G320V mutation in the hemojuvelin gene, the second case to carry this mutation in Romania, after another one recently published (19). We have not yet discovered the cause of iron overload in the remaining 5 patients.

CONCLUSIONS

Allelic frequency of the HFE mutant allele C282Y in Moldavia is about 1.75% and the expectancy of a severe form of hemochromatosis is one in about 800 people.

Three cases of hereditary hemochromatosis were found by looking for its phenotype among 549 patients: one was a HFE--C282Y homozygote, a second was a HFE-C282Y/H63D compound heterozygote and a third was a HJV-G320V homozygote.

AKNOWLEDGEMENTS

We wish to thank University Hospitals of Rennes and Lille (France) laboratories personnel for help and advice with genotyping.

NOUTĂŢI

Noradrenalina mai eficientă Şi mai bine tolerată decât dopamina în Şocul cardiogen

Administrarea unui vasopresor ca primă intenţie în tratamentul şocului este controversată. Atât în şocul septic cât şi în cel cardiogenic dopamina este cel mai des folosită. În absenţa unor studii clinice randomizate comparative, o serie de studii observaţionale recente subliniază obţinerea unor rezultate mai bune cu ajutorul noradrenalinei. Este şi motivul pentru care autorii, reanimatori din Belgia şi Spania, prezintă cel mai vast studiu clinic ce compară dopamina şi noradrenalina în tratamentul de primă intenţie al şocului. Diagnosticul a fost stabilit pe baza prezenţei unei hipotensiuni arteriale (presiunea arterială – PA medie <70 mm Hg, sau PA sistolică <100 mm Hg), asociată cu semne de hipoperfuzie tisulară (alterarea stării mentale, paloare tegumentară, scăderea debitului urinar, nivelul lactatului >2 mmol/L). În total, 1679 de subiecţi au fost randomizaţi în dublu orb între o perfuzie de dopamină sau de noradrenalină. În caz de rezultate insuficiente asupra PA cu doza maxim admisă (20 microg/kg/min pentru dopamină, respectiv 0,19 microg/kg/min pentru noradrenalină), adrenalina, dopamina sau vasopresina au fost administrate repetitiv. Toate celelalte tratamente (în special hidrocortizonul sau proteina C activată în cazul şocului septic) au fost administrate conform deciziei clinicienilor pentru fiecare caz în parte. Criteriul principal de evaluare a fost nivelul deceselor după 28 de zile de evoluţie. Caracteristicile celor 2 loturi au fost comparabile, cu un total de 62,2% de şocuri septice, 15,7% şocuri hipovolemice (hemoragice) şi 16,7% şocuri cardiogenice. Mortalitatea globală la 28 de zile a fost apropiată în cele 2 loturi, 52,5% decese în lotul cu dopamină, faţă de 48,5% în lotul cu noradrenalină ($p=0,10$). Toleranţa la noradrenalină a fost mai bună, cu 12,4% evenimente aritmice, faţă de 24,1% în cazul dopaminei ($p<0,001$). Nu au fost semnalate diferenţe pentru alte efecte secundare. Deşi s-ar putea aduce o serie de critici (cum ar fi asocierea în studiu a şocului cardiogen cu cel necardiogen, cele două având etiologii atât de diferite, sau faptul că o serie de metode terapeutice din şocul cardiogen – revascularizaţia percutană, contrapulsiunea aortică, asistenţa ventriculară stângă – nu sunt detaliate, alături de evaluarea administrării de vasopresină), prezentul studiu demonstrează că administrarea de noradrenalină ca medicaţie de primă intenţie în şocul cardiogen, departe de a creşte mortalitatea, este mai bine tolerată şi mai eficace (DeBacker D et al. Comparison of dopamine and norepinephrine in the treatment of shock. *N Engl J Med* 2010 ; 362 : 779-789).

THE INFLUENCE OF FRAILTY ON PATIENTS UNDERGOING MITRAL SURGERY (Abstract): The current tendency to ageing populations leads to increased degenerative pathology. Frailty, defined as a low capability to recover from pathogenic stressors due to aging related deterioration, plays a role in cardiovascular diseases as it increases operative risk and alters the postoperative prognosis and quality of life. Degenerative valve diseases occur more frequently in the elderly and register a clinical course in this group of patients. The aim of the current review is to evaluate the frailty scoring systems and their utility in cardiac surgery but also to highlight the particularities of surgical care in degenerative mitral valve diseases occurring in frail patients. Rigorous preoperative selection and functional status improvement is mandatory in order to maintain a relatively low complication rate. Long-term benefits regarding the duration and quality of life makes the operational risk acceptable by correcting a pathology that threatens the life expectancy of the elderly patients on short term. The geriatric patient's approach is multidisciplinary and involves creating a heart team based on the collaboration of geriatric doctors, anesthetists, cardiologists, internal medicine, cardiac surgeons and related specialties for early diagnosis, treatment and management of the complications. **Keywords**: FRAILTY, ELDERLY, MITRAL VALVE, SURGERY.

Nowadays, more elderly patients address to cardiac surgery clinics than never due to the increased life expectancy over the last century and because of population getting older. The aging process is not homogeneous, the biological age being different from the chronological age. One of the most problematic expression of population aging is frailty, a biological syndrome characterized by a decrease in physiological reserve and increased vulnerability to stress factors. Even if the prevalence is increasing with age, frailty is not synonymous with disability and comorbidity (1).

According to studies, the prevalence of frailty is higher in women than in men, women also having higher level of frailty compared to men of the same age (2, 3, 4). This finding can be explained by the greater burden of chronic disease, disability and poorer health status (5). It is well known that frailty is associated with a higher risk of death and that women, despite of having higher levels of frailty, live longer than men (4). This is called the 'sex-frailty paradox' and it is explained by the fact that

women have greater physiological reserve than men and it would enable women to acquire more deficits in multiple organ systems (6).

Aging is an evolutionary process characterized by extreme heterogeneity, with 3 categories of elderly people being delimited (7):

- Robust individuals with minimal or absent alteration of physiological functions without chronic or acute disease. This category represents 60-70% of the total elderly and should be assimilated to the general population;
- Dependent patients with severely progressive, complicated or disabling illnesses who require home assistance or those who live in an institutionalized setting - 5% of the elderly;
- Pre-fragile or fragile people in a precarious state of health and disease, autonomy and dependence; balance that can be disturbed at any time by stressors. The latent evolutive frail process becomes manifest or is accentuated by events such as illness, partner death, institutionalization or hospitalization. Thus, a cascade of events is initiated and exhausts the physiological reserves of the body, reduces its autonomy and speeds up death. Pre-fragile or fragile people account for about 25% of the elderly.

The phenotype of frailty

Frailty, the most problematic expression of population aging, is a widely debated concept in recent international literature as an approximate assessment of biological age. Frailty is defined as a biological syndrome that reflects a clinical condition characterized by a decrease in physiological reserve and vulnerability to stress factors, generically classified as iatrogenic (e.g. cardiac surgery), acute or chronic disease (7).

Disability is a term used to define the ability to perform day-to-day functional (ADL) and instrumental (IADL) activities. Frail patients exposed to stressors have an increased risk of decompensation, adverse clinical events, procedural complications, prolonged recovery, functional decline, disability, and increased mortality. In our opinion, frailty syndrome (fragility) precedes secondary disability and is a clinical status often associated with comorbidities typical to advanced age (8, 9).

The prevalence of frailty among elderly patients varies between 10 and 60% depending on the study, recent epidemiological research demonstrating a 2-fold increase in mortality and morbidity risk in a range of chronic cardiovascular diseases, acute coronary syndromes, heart failure, surgery, and percutaneous interventions (2).

In the last decade, frailty has been assessed as a predictor of unfavorable prognosis after cardiovascular interventions, with evidence of increased risk of morbidity, mortality, and institutionalization of frail patients compared to those of the same age group. This risk is not due to surgery. Conditions associated with long-term hospitalization such as prolonged immobilization have a negative impact on the development of complications compared to the actual intervention (10, 11, 12).

The pathobiology of frailty

Chronic inflammation is the common pathophysiological base of frailty syndrome and cardiovascular diseases (CVD) (9, 13, 14). In both instances, inflammatory markers such as neutrophils and monocytes, C-reactive protein, IL-6 and thrombotic markers including factor VIII and D-

dimers are identified. Proinflammatory status determinants, both in frailty and CVDare prolonged exposure to antigens, angiotensin 1 activation, obesity, insulin resistance, imbalance between antioxidants and pro-oxidants (15). The common biological pathway and mutual determinism in CVD and frailty syndromes are characterized by etiopathological and clinical elements that can determine and explain unfavorable cardiac or non-cardiac prognoses such as disability, prolonged hospitalization, increased mortality and morbidity (14). A frail patient is at risk of unfavorable outcome in case of invasive cardiovascular procedures and unsuccessful cardiac rehabilitation interventions as a counterpart to physical and mental exhaustion. Decreasing the physiological functional reserve of the human body with age increases the clinical picture of underlying conditions and accelerates the progression of the disease to multiple system organ failure (MSOF) syndrome development. Thus, the issue of biological age raises as a determinant of the operator's risk, regardless of the type of surgery. It is currently considered that chronological age is a major risk factor for postoperative mortality and morbidity in cardiovascular surgery even though the number and severity of comorbidities, that usually increase with chronological age, are factors that compete with perioperative prognosis on the mid and long-term in this high-risk group. Changes in age-related cardiac morphology concern alterations in intracellular and biochemical molecular pathways (16). They may affect the protein function, mitochondrial oxidative phosphorylation, excitatory coupling with cardiac muscle fibrillation, calcium ion kinetics, myofilament activation, cell matrix composition and regeneration (17).

Functionally, cardiac aging is characterized by decreased mechanical efficiency, reduced myocardial contractility, degenerescence of the valvular connective tissue, decreased myocyte number, increased myocyte size, accelerated myocardial cell apoptosis rate, decreased inotropic and adrenergic-mediated contractile response. The aging process is associated with functional and structural changes in coronary vascularity, with an impact on myocardial perfusion. Reduced coronary artery reserve with aging may interfere with reflex vasodilation and determine decreased cardiac output and myocardial blood flow (18). Decreased vasodilatation may be due to alteration of epithelial endothelial component, increased resistance in coronary territory, decreased stimulation and release of nitric oxide in coronary endothelium, but also to the vasoconstrictive effect of increased endothelin 1 (ET-1) plasma levels in the elderly (19). From a morphological point of view, large arteries expand and increase their parietal thickness mainly due to changes in the parietal matrix (fig. 1).

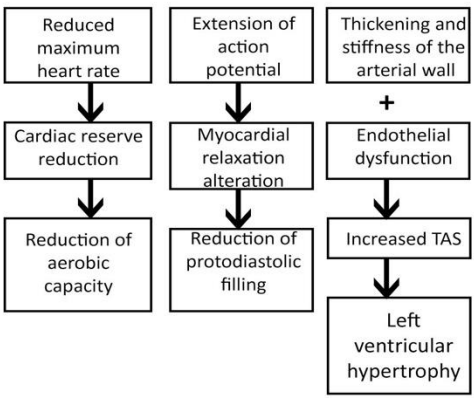

Fig. 1. The pathobiology of frailty syndrome

These changes increase vascular stiffness and act as a trigger factor for a high systolic blood pressure and pulse wave velocity. The final stage is the increase of aortic impedance and mechanical loading, which seems to diminish the cardiac performance (18).

Frailty scores

There are several factors contributing to the exacerbation of frailty syndrome in patients with CVD. In the literature there are described up to 20 assessment tools, most of them being adjacent to the phenotypic domain of frailty syndrome.

Despite of being a widely debated concept, a consensus in defining frailty has not been reached. According to Fried's frailty phenotype, known as the Cardiovascular Health Study Index (CHSI), frailty is defined by the presence of three or more of the following criteria:

- Weight loss: unintentional loss of more than 4.5 kg in the past year or weight at examination <10% of the weight registered at the age of 60 years;
- Exhausting: self-reported fatigue or felt unusually tired or weak in the past month;
- Low physical activity;
- Slow walking speed: 4 m >7 s if height <159 cm or >6 s if height >159 cm;
- Weakness: low grip strength (20).

Pre-frail is defined as scoring one or two out of the five criteria. This definition does not include the measures of mental and cognitive health which are important parameters in frailty. Compared to Fried's model of frailty, the Study of Osteoporotic Fractures (SOF) frailty index added the domain of cognitive decline. Frailty is classified as the presence of more than 2 components from shrinking, exhausting and low mobility (21).

In cardiac surgery, the operative risk is commonly assessed using the European System of Cardiac Operative Risk Evaluation (Euro SCORE)and the Society of Thoracic Surgeons (STS) score (22).

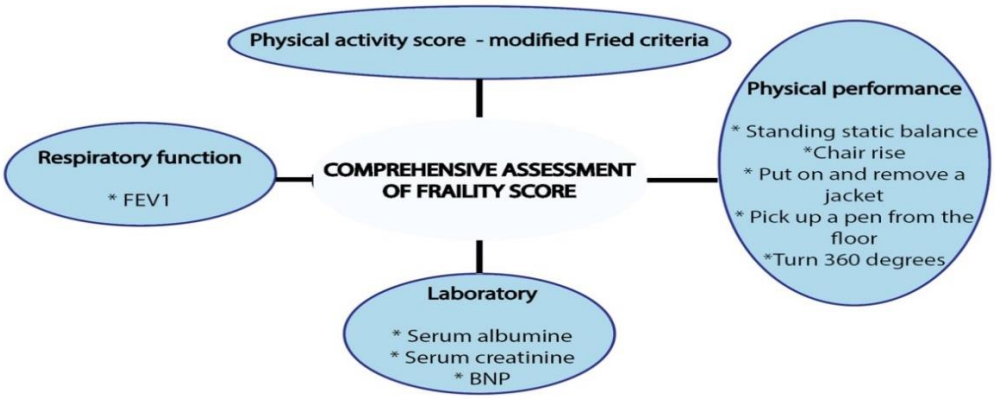

Fig. 2. Comprehensive Assessment of Frailty score

To measure the perioperative risk of elderly patients receiving elective cardiac surgery, there is a "Comprehensive Assessment of Frailty" (CAF) score that is used concurrently with conventional risk scores in cardiovascular surgery as a predictive factor in clinical practice. The CAF should be used during the pre-operative

period, minimum 5 meters walking test, being a simple and powerful tool for evaluating the frailty syndrome. The score incorporates physical ability, patient phenotype, the Fried criteria and laboratory values (fig.2) (22). The score shows significant statistically correlation within 30 days mortality. The disadvantages of CAF score are that it takes about 10 to 20 minutes to perform it and needs special equipment (23). The same authors described FORECAST, a score that includes the most predictive items of the CAF-score like 'chair rise', 'weakness', and 'creatinine' and takes maximum 5 minutes to perform. After one-year follow-up, in the estimation of one-year mortality risk, the FORECAST score had better results than the Euro SCORE and the STS score (24).

Ageing mitral valve in frail patients

Almost 10% of patients over 75 years register significant mitral valve regurgitation because of the natural aging process of the mitral valve. It has a very high incidence, being classified as second, after the aortic valvular disease (11). There are many uncertainties regarding the benefits of mitral valve surgery in elderly patients, but recent studies show that it can improve their general health status, with a positive impact on the quality of life.

The etiology of mitral regurgitation in the elderly is primarily degenerative. These lesions are therefore usually accessible to repair. Some studies have reported a mortality rate associated with mitral valve surgery in elderly patients greater than 15%. However, recent articles show that this surgery can be performed in patients over 80 years with good results and mortality less than 5% (25).

Peri and postoperative complications also vary depending on the type of surgery. They are less important in mitral valve repairment compared to replacement, due to better preservation of left ventricular function and to prevention of specific problems with different types of valve substitutes. The choice of valve prosthesis in case of repairment must consider the existence of potential contraindications to oral anticoagulation. The use of bio prostheses is recommended after 70 years on the one hand, because of their durability not exceeding the long-term survival of these patients and on the other hand, because of the potential risk of hemorrhage under anticoagulants in this population.

The surgical risk in frail patients is counterbalanced by good functional results on the long term and by obtaining a survival time close to the life expectancy observed in the general population of the same age (26).

Nowadays, modern therapeutic approaches have emerged such as implants for mitral reconstruction (Mitra Clip) and implants for mitral replacement (Transcatheter Mitral Valve Replacement - TMVR). From a technical point of view, Mitra Clip has been designed for the treatment of secondary (or functional) mitral regurgitation; in clinical practice, however, it is increasingly used in cases of primary (structural) mitral regurgitation in frail and very old patients (27).

The current use of transcatheter aortic valve implantation (TAVI) should serve as an example for the further development of transcatheter techniques for treating mitral valve diseases. These innovations will most likely result in improved and faster management of mitral insufficiency. In a second step, depending on the results, the corresponding recommendations will be

adapted to allow the planning of the most appropriate possible treatment at an early stage of the disease. A Heart Team is mandatory for selecting the most appropriate treatment.

CONCLUSIONS

Our research draws attention to comorbidities such as frailty, that occurs very commonly in elderly patients and requires a different surgical course. Degenerative damage to heart valves occurs in all elderly patients, but the need for surgical interventions is only needed in patients with class IV heart failure. The important outcomes of the frailty patients after cardiac surgery are to improve the functional survival and the quality of life. It is well known the association between frailty and the rising number of complications, longer length of stay in hospital and mortality. Therefore, it is important to develop a practical standard score in order to identify the frailty patients at high risk of poor postoperative outcomes and to improve the patient's selection for cardiac surgery.

MACROPHAGE-MEDIATED NUTRITIONAL IMMUNITY AGAINST *RHIZOPUS* SPP

A study by Andrianaki AM *et al*. aims to describe the pathogenic mechanisms of mucormycosis, a severe respiratory infection caused by *Rhizopus* spp. The study shows that *Rhizopus* spp. can persist inside alveolar macrophages. This is explained by melanin-induced inhibition of phagosome maturation. The mechanism permits the microorganism to evade phagocytosis. Iron assimilation from the host plays an important role in the life cycle of *Rhizopus* spp. The study shows that host immunity against *Rhizopus* is mediated by iron limitation inside macrophages, a defense strategy known as nutritional immunity. Dual RNA-sequencing technique and functional studies were used to identify both the fungal and host modulators of iron homeostasis in macrophages that play a role in promoting invasive fungal growth. (Andrianaki AM, Kyrmizi I, Thanopoulou K, *et al*. Iron restriction inside macrophages regulates pulmonary host defense against Rhizopus species. *Nat Commun* 2018; 9(1): 3333).

IMPACT OF ACROMEGALY ON THE CARDIOVASCULAR SYSTEM

IMPACT OF ACROMEGALY ON THE CARDIOVASCULAR SYSTEM (Abstract): Cardiovascular manifestations occur in 60% of patients with acromegaly. The severity of the structural and functional heart abnormalities mainly depends on the levels of growth hormone and insulin-like growth factor 1 and the time between disease onset and diagnosis. Long-lasting elevated hormone levels are responsible for acromegalic cardiomyopathy, valvular disease, arrhythmias, hypertension, coronary artery disease and even congestive heart failure. We highlight the tremendous impact of hormone imbalance upon the heart structure and function in order to raise awareness upon the fact that cardiovascular disease has become the leading cause of mortality in patients with acromegaly. We draw attention to the fact that acromegaly is more than an endocrine disease and we emphasize the need for a multidisciplinary approach of the acromegalic patient, of which the cardiologist must be part.
Keywords: ACROMEGALY, CARDIOMYOPATHY, ARRITHMIAS, HYPERTENSION.

Acromegaly is a rare endocrine disorder caused by prolonged and excessive secretion of growth hormone (GH) by the pituitary gland. GH exerts its effects either directly or indirectly, through its peripheral effector insulin-like growth factor 1 (IGF-1). Long-lasting high levels of these hormones lead to enlargement of organs and soft tissues.

Cardiovascular manifestations occur in 60% of patients. The cardiovascular impact of hormonal imbalance manifests as cardiomyopathy, valvular disease, arrhythmias, hypertension, coronary artery disease and even congestive heart failure if acromegaly is uncontrolled. Cardiovascular disease has become the leading cause of mortality in patients with acromegaly (1), especially in the presence of diabetes mellitus and obstructive sleep apnea, which are highly prevalent in these patients.

Acromegalic cardiomyopathy

Cardiac involvement in the absence of other identifiable causes of cardiomyopathy defines acromegalic cardiomyopathy. It

affects 3% of patients with acromegaly. The severity of the structural and functional heart abnormalities mainly depends on the levels of GH and IGF-1, and the period of time when the heart was exposed to elevated hormone levels (the time between disease onset and diagnosis) (2).

Acromegalic cardiomyopathy evolves in three stages (3). The characteristics of the first stage are enhanced myocardial contractility, increased cardiac output and decreased peripheral vascular resistance. It is the so called "hyperkinetic syndrome" (4). IGF-1 increases Ca^{2+} influx and raise peak Ca^{2+} levels in cardiomyocytes and also increases the sensitivity of myofilaments to Ca^{2+}, thus resulting in increased inotropism and a hyperkinetic heart (5).

The intermediate stage is characterized by biventricular hypertrophy, interstitial fibrosis, diastolic dysfunction and impaired systolic function during exercise (4, 6). The ventricular walls are concentrically thickened due to a relative increase in myocyte size. Usually, hypertrophy of the left ventricle is more significant, but the right ventricle can be equally involved. Hypertrophy without ventricular dilation is an early feature of the disease. Studies show that up to 54.5% of young patients (<40 years old) with active acromegaly of 3-7-year duration had echocardiographic evidence of left ventricular hypertrophy. This percentage rises up to 72.2% in patients aged 41-60 years and disease duration of 5-15 years (7). Interstitial fibrosis, consequence of a markedly increased myocyte apoptosis (495 fold higher than normal) is associated with extracellular collagen deposition and myofibrillar derangement (8). The damaged heart architecture has a negative impact on ventricular function. Ventricular relaxation is impaired, and compliance is reduced. These changes lead to diastolic dysfunction. Left ventricular filling is insignificantly impaired at rest but is associated with reduced exercise tolerance.

In the final stage, severe enlargement of cardiac chambers and systolic and diastolic dysfunction occur (4). The peripheral vascular resistance increases. This late stage ends in congestive heart failure.

Successful treatment of acromegaly is associated with a decrease in left ventricular mass and with the improvement of diastolic and systolic function (9). A beneficial effect of treatment has also been reported in patients with acromegalic cardiomyopathy and congestive heart failure (10). Cardiac function improvement is greatest in young patients with short disease duration, in which the early diastolic changes are completely reversible under treatment.

Arrhythmias in acromegaly

Patients with acromegaly have a high incidence of arrhythmias (11). Cardiac arrhythmias and sudden cardiac death are the most common causes of increased mortality in acromegaly. Abnormal heart architecture, with areas of hypertrophied myocytes separated by fibrosis and cellular infiltration provide de substrate for the structural uncoupling of cardiac myocytes. Other mechanisms like phenotypic changes in membrane proteins and conduction system disease are also involved (12), but fibrosis is mainly responsible for the disorganized and asynchronous electrical activity in ventricles, favoring reentrant events.

The electrophysiological abnormalities have a wide range of manifestations, from ectopic beats, paroxysmal atrial fibrillation,

paroxysmal supraventricular tachycardia, sick sinus syndrome, to ventricular tachycardia and bundle branch blocks (6,13). One study reported conduction disorders in up to 41% of patients with acromegaly (14).

Arrhythmic events are present at rest, but especially during exercise. The frequency and severity of ventricular arrhythmias correlate with clinical activity score, duration of acromegaly and left ventricular mass, but not with hormone levels (12). This is supported by several studies (14,15) that showed that ventricular arrhythmias were as frequent before as after treatment of acromegaly, implying that fibrous tissue infiltration had resulted in permanent irreversible scarring.

Hypertension in acromegaly

Hypertension is the cardiovascular disease most frequently encountered in acromegaly patients, with a reported prevalence ranging from 25 to 50% (5). The diastolic blood pressure is usually elevated (16). The pathogenesis of HTA in acromegaly is multifactorial, including increased vascular resistance, increased plasma volume, alterations in renin-angiotensin-aldosterone system and insulin resistance (9). Long-lasting high GH levels stimulate smooth muscle cell growth, thereby increasing peripheral vascular resistance and blood pressure (5). Moreover, GH blocks insulin actions at several levels, leading to insulin resistance (17), which is associated with low nitric oxide production and high activity of the vascular renin-angiotensin-aldosterone system (9). The impaired endothelium-dependent vasodilation, the increased vascular response to angiotensin II and the exaggerated sympathetic-mediated vasoconstrictor response contribute in various degrees to the increase of arterial peripheral resistance (18, 19).

GH can cause sodium retention through three mechanisms: activation of Na^+-K^+ ATP-ase pump in the renal tubules (20), activation of the renin angiotensin system and inhibition of atrial natriuretic peptide release (21). Due to its antinatriuretic action, GH increases extracellular volume and by consequence blood pressure.

It is important to highlight the fact that hypertension is an independent risk factor for cardiac morbidity in acromegalic patients and an important negative prognostic factor for mortality in these patients.

Valvular disease in acromegaly

Few data are available regarding valvular disease in acromegaly because it rarely occurs (11). Mitral, aortic and tricuspid regurgitation have been reported in the late stages of disease, usually as a result of ventricular remodeling. One small study (22) including 32 patients with acromegaly found aortic regurgitation in 31%, mitral regurgitation in 47%, and tricuspid regurgitation in 37% of the cases. Another study (23) described mitral and aortic valvular annulus fragility and leaflet disarray, accompanied by functional regurgitation.

Coronary artery disease in acromegaly

Data regarding coronary artery disease (CAD) in acromegaly are limited and conflicting (11,24). There is much evidence that acromegaly per se does not increase the risk of CAD (25). Calculations based on the European Society of Cardiology risk score and Framingham risk score showed a

low 10-year CAD risk (9). These findings were supported by studies using coronary artery calcium (CAC) score with the purpose of identifying early-stage coronary atherosclerotic disease in asymptomatic patients, in which low scores have been obtained.

Conversely, a study (26) that evaluated the risk factors and CAC score showed that 41% of acromegalic patients are at risk for coronary atherosclerosis and that coronary calcifications were evident in about half of cases. These findings are consistent with the fact that acromegaly is an insulin-resistant state, associated with a high prevalence of diabetes mellitus and hyperlipidemia, which contribute to the cardiovascular risk.

CONCLUSIONS

Our research shows that acromegaly is far more than an endocrine disease. We highlight the major influence of GH and IGF-1 on cardiovascular system. Morphological and functional heart abnormalities induced by long-lasting high hormone levels have a tremendous impact upon mortality, morbidity and quality of life in acromegalic patients. We encourage the close collaboration between endocrinologists and cardiologists in order to ensure an early diagnosis and adequate monitoring of cardiovascular consequences of acromegaly. Since many parameters of cardiac function change with acromegaly treatment, we emphasize the need of periodical cardiovascular assessment.

2. Disciplina de Farmacologie

CLINIC AND EPIDEMIOLOGIC RESEARCHES ON CARDIOVASCULAR COMPLICATIONS IN PATIENTS WITH METABOLIC SYNDROME (Abstract): Our study aims to identify correlations between the metabolic syndrome and cardiovascular diseases determinism. **Material and methods**: A retrospective study was carried out on a sample of 1463 patients of which 734 patients met the diagnostic criteria of cardiometabolic syndrome, admitted in the Clinic of Cardiovascular Rehabilitation, Rehabilitation Hospital, Iasi, between 01.01. 2009-31.12.2009. **Results**: The incidence of cardiometabolic syndrome has a soft predominance on the group 40-59 years (61.66%). The high level of hypertension was found in the patients group 48-69 years (53.70%) and lowest in the patients group 25-38 years (11.35%) (p=0.001). The coronary heart diseases showed a significant difference between age groups: 48-69 years (41.80%), compared to 25-38 years (7.55%) (p=0.003). Heart failure is part of the same age distribution curve (45%, 6.8%) (p=0.02). **Conclusions**: The metabolic syndrome is a predictor of the occurrence and development cardiovascular disease. **Key words**: METABOLIC SYNDROME, CARDIOVASCULAR DISEASE, INCIDENCE, HYPERTENSION, HEART FAILURE

Sindromul metabolic reprezintă o tulburare complexă a metabolismelor organismului ce însumează o combinaţie de factori precum obezitatea, rezistenţa la insulină, hipertensiunea arterială şi dislipidemiile, precum hipertrigliceridemie, creşterea acizilor graşi liberi, scăderea HDL colesterolului şi creşterea LDL colesterolului.

De-a lungul timpului, sindromul metabolic a primit diverse definiţii. Prima încercare a fost realizată în 1923 de către suedezul E. Kylin, care a definit sindromul cardiometabolic ca o afecţiune la care coexistă hipertensiunea arterială (HTA), hiperglicemia (HG) şi guta, numindu-l „sindrom de hipertensiune-hiperglicemie-hiperuricemie". Raven în 1988 considera sindromul metabolic ca o interrelaţie între stilul de viaţă sedentar, dieta hipercalorică şi factorii genetici, acestea determinând apariţia dezechilibrelor manifeste prin: hiperglicemie, obezitate abdominală, hipertrigliceridemie, reducerea nivelului seric al HDL şi hipertensiune arterială (HTA). Ulterior definiţia a fost completată, updatată de diverse forumuri precum OMS (Organizaţia Mondială a Sănătăţii) în 1998, WHO – (World Health Organization), 1999, ATP III (Third Report of the National Cholesterol Education Program's Adult Treatment Panel), în Executive Summary of the NCEP, 2001. În octombrie 2009, a fost adoptată o definiţie ce include toate criteriile menţionate anterior, la care au conlucrat Comitetului Operativ pentru Epidemiologie şi Prevenţie al International Diabetes Federation (IDF), National Heart, Lung and Blood Institute

(NHLBI), Federaţia Mondială a Inimii, Societatea Internaţională de Ateroscleroză, American Heart Association (AHA) şi Asociaţii Internaţionale de Studiu a Obezităţii, în încercarea de a elimina câteva din confuziile apărute în identificarea pacienţilor cu sindrom cardiometabolic (SCM).(1, 2)

Deşi sindromul metabolic este o afecţiune cunoscută şi facil de diagnosticat, complicaţiile ce derivă sunt tot mai numeroase şi cu un impact deosebit în creşterea incidenţei afecţiunilor cardiovasculare. Bolile cardiovasculare (BCV) rămân pe primul loc în determinismul morbimortalităţii la nivel mondial. La sfârşitul anului 2000, BCV reprezentau cauza directă a peste 4.35 mil decese la nivel european (43% bărbaţi, 57% femei). Mai mult de 300 mil. persoane din lumea întreagă prezintă un indice de masă corporal (IMC) > 30 kg/m^2, iar procentul acestora este în continuă creştere (2,3).

Ghidul european al ESC (European Society of Cardiology) de prevenţie şi recuperare al BCV atrage atenţia asupra comorbidităţilor determinate de factorii de risc tradiţionali şi non-tradiţionali cardiovasculari şi metabolici.

MATERIAL ŞI METODĂ

Studiul nostru îşi propune identificarea corelaţiilor existente între sindromul cardiometabolic şi determinismul afecţiunilor cardiovasculare pe o populaţie reprezentativă pentru zona Moldovei. Prin acest studiu se doreşte atragerea atenţiei asupra necesităţii de evaluare a pacientului cu sindrom metabolic şi din punct de vedere al afectării cardiovasculare.

Studiul s-a desfăşurat în cadrul Clinicii de Recuperare Cardiovasculară, a Spitalului de Recuperare Iaşi în perioada 01.01.2009--31.12.2009 şi a inclus un număr de 1463 pacienţi, din care 752 (51.40%) au îndeplinit criteriile.

Criteriile de includere în studiu au fost

- perimetrul abdominal >94 cm la bărbaţi, >80 cm la femei
- trigliceridemie >150 mg/dl sau tratament specific ;
- HDL-colesterolemie <40 mg/dl la bărbaţi, <50 mg/dl la femei sau tratament specific ;
- TAS >130 sau TAD >85 mmHg sau tratament specific ;
- glicemia á jeun >100 mg/dl sau DZ tip 2 în diagnostic.

Studiul de faţă aduce argumente cu privire la creşterea incidenţei sindromului metabolic în populaţia generală – 735 (50, 23%) pacienţi din numărul total – 1463 pacienţi adresat Clinicii de Recuperare Cardiovasculară.

Prelucrarea şi interpretarea datelor a fost realizată prin metode epidemiologice (ancheta), statistico-matematice (p, deviaţie standard (DS), tendinţă) şi computerizate.

REZULTATE ŞI DISCUŢII

1. *Repartiţia pe sex*. În cadrul studiului nostru se păstrează aceeaşi tendinţă globală de creştere a obezităţii în populaţia generală, cu predominanţa la sexul feminin (58.37%). Diferenţa dintre sexe este uşor semnificativă. Datele clinico-epidemiologice existente în literatură confirmă afectarea preponderentă a sexului feminin, obezitatea fiind influenţată atât de factorii socio-economici, comportamentali, factorii de mediu cât şi de factorii naturali.

Mai mult, cercetările recente au relevat existenţa unei legături între insulinorezistenţă (IR) şi dereglările hormonale la femei. Astfel, unele studii au demonstrat incidenţa mai mare a dezvoltării DZ tip 2 la femeile cu oligomenoree, aproximativ 82% din femeile cu DZ tip 2 prezentau polichistoză ovariană. În premenopauză femeile prezintă un risc crescut de dezvoltare a HTA, iar în perioada climacterică frecvenţa dezvoltării HTA creşte până la 52,4%. Această creştere s-ar datora diminuării efectului pozitiv al estrogenilor asupra funcţiei endoteliale, care

TABELUL I

Parametrii estimaţi în testarea asocierii sexul pacienţilor vs. diagnostic

	Chi-pătrat χ^2	**df**	**p** *95% interval de încredere*
Chi-pătrat - χ^2	1,535857	df=1	p=0,21524
Coeficient de contingenţă	0,0347956		
Coeficient de corelaţie	0,0875777		p=0,21555

TABELUL II

Parametrii estimaţi în testarea asocierii mediul de provenienţă vs. diagnostic

	Chi-pătrat χ^2	**df**	**P** *95% interval de încredere*
Chi-pătrat - χ^2	6,136817	df=1	p=0,01324
Coeficient de contingenţă	0,4704490		
Coeficient de corelaţie	0,31836212		p=0,01192

TABELUL III

Valorile medii ale gradelor de severitate a HTA în funcţie de grupa de vârstă

GRUPA VÂRSTA	**HTA - Means**	**HTA - Std.Dev.**
20-39 ani	1,826087	0,576208
40-59 ani	2,115942	0,607217
60-79 ani	2,034483	0,700013
80-99 ani	2,085714	0,631145
Toate grupele	2,055319	0,634752

corija spectrul lipidic, prin creşterea HDL colesterolului şi scăderea LDL colesterolului, precum şi ameliorarea reactivităţii acetilcolinice vasculare, inclusiv în arterele coronare, stimularea sintezei NO–sintazei şi creşterea nivelului bazal al NO (4). Karelis et al. au demonstrat că descreşterea sensibilităţii insulinice este asociată cu creşterea graduală a numărului de caractere ale SM (5).

2. *Repartiţia pe medii de provenienţă* a evidenţiat o diferenţă uşor semnificativă între mediul urban (60.25%) şi mediul rural. Mediul urban, prin implicaţiile stilului de viaţă şi a factorilor de risc ridicaţi (condiţii de viaţă şi muncă, factori nutriţionali, poluarea, stresul, etc.) face preponderentă dispunerea în mediul urban vs. rural a obezităţii.

3. *Repartiţia pe grupuri de vârstă*. La pacienţii cu sindrom cardiometabolic (SCM) de notat este ponderea semnificativă în cadrul criteriilor de încadrare a circumferinţei abdominale, colesterolului, a HTA (cel mai frecvent grad I-III) şi a hiperglicemiei a jeun. Îngrijorător este faptul că procentul cel mai mare de pacienţi cu sindrom metabolic este pe intervalul de vârstă 40-59 ani, deci la nivelul populaţiei active (61,66%).

Rezultatele trialurilor clinice realizate de Women's Health Initiative (WHI) au evidenţiat existenţa hiperinsulinismului la 75% din cazuri. Nivelele înalte ale insulinemiei bazale au fost corelat atât pozitiv cu creşterea vârstei, IMC, perimetrul abdominal, cât şi negativ cu nivelele mai înalte de activitate recreaţională. Manco et al. a observat nivele mai joase ale sensibilităţii la insulină şi nivele mai înalte de insulinemiei bazale la femeile în premenopauză, direct proporţională cu creşterea în vârstă, a masei adipoase şi nivelurile TG (factori de risc determinanţi pentru BCV) (5, 6)

4. Impactul HTA. Datele din literatură conform cărora România este pe primul loc prin procentul de 40% al hipertensivilor în populaţia generală sunt confirmate şi în cadrul studiului nostru. Astfel, se constată ponderea importantă a HTA de orice grad şi pentru toate grupele de vârstă. Aproximativ 50% hipertensivi au hiperinsulinism şi până la 75% indivizi cu DZ tip 2 sunt hipertensivi. Esenţa legăturii între HTA,

TABELUL IV
Analiza comparativă a severităţii HTA în funcţie de grupa de vârstă prin metoda One Way ANOVA

	SS - Effect	MS - Effect	SS - Error	MS - Error	F	p
HTA	1,553957	0,388489	92,72689	0,403	0,963	0,001

insulinorezistenţă (IR) şi BCV este complicată. Explicaţia acestui procent ridicat ar putea fi mecanismul hipertensinogen al hiperinsulinismului, prezent la pacienţii cu sindrom cardiometabolic. Hiperinsulinismul determină o creştere a retenţiei de Na şi apă în organism, prin creşterea reabsorbţiei tubulare, are efect vasodilatator asupra peretelui vascular, vasoconstrictor la nivelul capilarelor, reglator asupra metabolismelor Na şi Ca prin acţiune asupra sistemului renină-angiotensină. Această supresie a natriurezei indusă de insulină are ca rezultat creşterea volumului sanguin, deci a tensiunii arteriale. De asemenea, hiperinsulinismul poate induce o hiperexpresie a endotelinei I. Pacienţii cu hiperinsulinism prezintă un tonus simpatic crescut, care va determina vasoconstricţie, deci creşterea rezistenţei vasculare periferice, toate acestea contribuind la apariţia şi menţinerea HTA. Deci, HTA este multifactorială şi faptul că HTA este inclusă printre criteriile de descriere este din cauza prezenţei extrem de răspândite a HTA în cadrul SCM (6).

În cadrul studiului nostru, de subliniat ponderea importanta a HTA grad I şi III nediagnosticată la grupa de vârstă 26-50 ani cu implicaţii în dezvoltarea comorbidităţilor. Diferitele grade ale nivelului TA pot afecta profilul de risc cardiovascular al acestor pacienţi, care evident va fi mai înalt la indivizii cu nivele tensionale mai înalte (tab. III).

Un rol dominant în corelaţia dintre HTA şi obezitate îl are hiperactivitatea sistemului nervos simpatic (SNS). Legăturile dintre etiopatogenia obezităţii şi SNS sunt multiple şi în multe cazuri nu sunt elucidate până la capăt. Leptina, un hormon secretat de adipocite nu doar reglează apetitul ci joacă şi un rol important în cheltuielile de energie prin activarea SNS. Leptinemia este înaltă la pacienţii obezi, ceea ce are un rol important în cauzarea hiperreactivităţii SNS. Din contra, la pacienţii obezi receptorii apetitului sunt rezistenţi la reglarea centrifugă a sistemului nervos central (SNC), ceea ce duce la creşterea leptinemiei. Surplusul de norepinefrină, ca o consecinţă a hiperactivităţii SNS la obezi, implică afectarea rinichilor ca efectori majori ai activităţii SNS. Creşterea acţiunii SNS asupra rinichiului, duce de la sine la creşterea reţinerii de sare şi apă şi respectiv la HTA. Comprimarea rinichiului de către depozitele de grăsimi, modifică structura acestuia, care poate duce după sine la HTA prin stimularea nervilor simpatici renali aferenţi şi prin inducerea HTA renovasculare (7).

Relaţia cauzală dintre HTA şi obezitate poate fi biderecţională. La indivizii cu predispoziţie la HTA, creşterea activităţii SNS este asociată cu reglarea centrifugă a receptorilor ß-adrenergici, ce determină afectarea termoreglării şi tendinţa de creştere a circumferinţei abdominale (CA).

5. Impactul SCM asupra frecvenţei cardiace. Sindromul metabolic, denumit şi sindromul X, sindromul rezistenţei la insulină, sindromul hipertensiunii sau sindromul excesului de catecolamine prin mecanismul său central de creştere a tonusului simpatic determină creşterea frecvenţei cardiace - factor major al creşterii consumului de oxigen şi a necesităţilor metabolice. Deci, influenţa hiperinsulinismului se reflectă şi asupra frecvenţei cardiace. Aceasta creştere este direct proporţională cu creşterea debitului cardiac.

Studiile anterioare au demonstrat că activitatea metabolică, debitul cardiac şi frec-

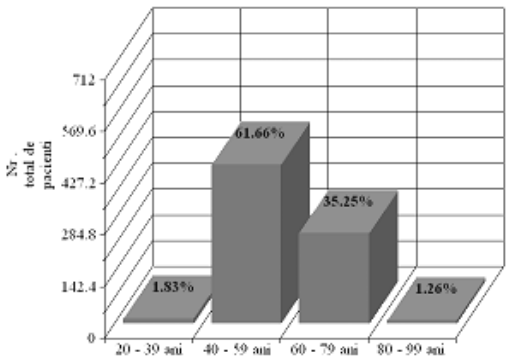

Fig. 1. Repartiţia pe grupe de vârstă a SCM

venţa cardiacă sunt crescute la pacienţii obezi, proporţional cu surplusul de greutate. Deci, creşterea frecvenţei cardiace s-ar datora acţiunii sinergice a celor doi factori implicaţi în evoluţia sindromului metabolic : hiperinsulinismul şi obezitatea (8).

În cadrul studiului nostru, se confirmă ipotezele anterioare, numărul pacienţilor cu sindrom metabolic şi frecvenţă cardiacă ridicată FC > 80/min fiind semnificativ.

6.Impactul SCM asupra aritmiilor cardiace. Cercetările recente anatomopatologice, macro- şi microscopică asupra cordului la pacienţii obezi relevă o creştere a greutăţii cordului, cu dilatare şi hipertrofie concentrică de ventricul stâng. Aceste modificări predispun la apariţia aritmiilor ectopice, în parte datorate unei disfuncţii vegetative cardiace. Având în vedere factorii de risc asociaţi sindromului metabolic FC > 80/min şi masa VS > 270 g, ruptura plăcii de aterom este o complicaţie bine cunoscută, la pacienţii cu boală coronariană. În cadrul studiul nostru, la eşantionul de pacienţi cu vârsta cuprinsă între 26-50 ani 9,52%(4 bărbaţi) şi 7,83%(4 femei) au fost diagnosticaţi cu aritmie. În eşantionul de pacienţi cu vârsta cuprinsă între 51-75 ani 24,60% (47 bărbaţi) şi 21,72% (58 femei) au fost diagnosticaţi cu aritmie. Aceeaşi tendinţă a fost observată la eşantionul de pacienţi cu vârsta peste 75 ani 55,55% (5 bărbaţi) şi 59,09% (13 femei au fost diagnosticaţi cu aritmie (9).

7. Impactul SCM asupra insuficientei cardiace. Studii realizate prin cateterism cardiac la pacienţii obezi fără HTA arată că deşi se înregistrează creşteri ale presiunilor de umplere, telediastolice, a dimensiunilor cavităţilor cordului, precum şi a presiunii capilare pulmonare, performanţa ventriculului stâng este în limite normale. La pacienţii cu obezitate de grad II - III sau la cei ce asociază HTA, este afectată atât funcţia sistolică cât şi diastolică a ventriculului stâng, atingând grade diferite de insuficienţă cardiacă reversibilă cu scăderea în greutate. Cardiomiopatia obezilor se datorează iniţial creşterii volumului circulant şi a debitului cardiac pentru ca ulterior să fie agravată de HTA, insuficienţă coronariană şi tulburări respiratorii. Hipertrofia ventriculului stâng reduce complianţa cordului cu creşterea presiunilor de umplere ale ventriculului stâng şi risc de edem pulmonar acut. Deşi în condiţii de repaus performanţele ventriculului stâng sunt în limite normale, adaptabilitatea la efort este slabă, creşterea debitului cardiac nu se poate face decât pe seama creşterii frecvenţei cardiace întrucât volumele de ejecţie nu se pot adapta (8, 9).

În cazul studiului nostru, la eşantionul de pacienţi cu vârsta cuprinsă între 26-50 ani 14,28% (1 bărbat) şi 12,5% (1 femeie) aflaţi sub tratament hipolipemiant au fost diagnosticaţi cu insuficienţă cardiacă. În eşantionul de pacienţi cu vârsta cuprinsă între 51-75 ani 31,41% (60 bărbaţi) şi 21,72% (58 femei) au fost diagnosticaţi cu insuficienţă cardiacă. În eşantionul de pacienţi cu vârsta cuprinsă peste 75 ani toţi bărbaţii şi 66,66% (2 femei) au fost diagnosticaţi cu insuficienţă cardiacă.

CONCLUZII

Sindromul metabolic reprezintă o problemă de mare actualitate prin creşterea alarmantă a prevalenţei acestuia, precum şi datorită complexităţii mecanismelor fiziopatologice, riscului de apariţie a compli-

caţiilor şi abordării terapeutice. O pondere importantă a pacienţilor cu HTA, gradul I - III, asociază SCM, precum şi alţi factori de risc pentru evoluţia BCV. Cel mai mare impact în apariţia şi dezvoltarea BCV îl are insulinorezistenţa, care poate avea diferite grad de manifestare – de la ascunsă sau latentă până la slab pronunţat, la care se adaugă prezenţa altor tulburări metabolice precum obezitatea, hiperleptinemia, dislipidemia, hiperuricemia, tulburarea sistemului hemostazei (hipofibrinoliză şi hipercoagularea), afectarea sistemului imun prin imunodeficienţă secundară şi influenţa postmenopauzei la femei (10,11).

Studiul nostru îşi propune identificarea corelaţiilor existente între sindromul cardiometabolic şi determinismul afecţiunilor cardiovasculare pe o populaţie reprezentativă pentru zona Moldovei. Astfel, se remarcă o creştere a incidenţei insulinorezistenţei şi a sindromului cardiometabolic pe 2 intervale de vârstă: 25-50 şi 51-75 ani (la aceştia din urmă, este necesară introducerea în cadrul programelor terapeutice şi de recuperare).

Grupul ţintă de evaluat şi introdus în programe de prevenţie şi recuperare, aşa cum o arată procentele, se situează între 25-50 ani la care schimbarea stilului de viaţă, diminuarea factorilor de risc, reevaluarea periodică în cadrul unui program de specialitate va duce nu numai la diminuarea severităţii comorbidităţilor, ameliorarea prognosticului in timp, ci şi la îmbunătăţirea semnificativă a calităţii vieţii pacientului.

Asocierea tulburărilor metabolice într-un lanţ comun în care insulinorezistenţa tisulară nu numai că înrăutăţeşte manifestarea clinică a lor, dar şi le oferă un caracter specific determină apariţia şi dezvoltarea comorbidităţilor asociate sindromului cardiometabolic, din care afectarea cardiacă are o pondere majoritară. Deci, diagnosticul precoce al SCM la pacienţii hipertensivi cu prezenţa măcar a unuia din factorii de risc metabolici ai BCV este extrem de necesară şi raţională pentru aprecierea ulterioară a riscului sumar la pacienţii respectivi şi posibilitatea normalizării valorilor tuturor componentelor de bază ale SCM.

DIFFERENCES IN TUBERCULOSIS BASED ON GENDER PECULIARITIES (Abstract)**:** The relationship between the gender peculiarities and tuberculosis is under-recognized due to a complex of factors. The **aim** of the study was to assess the impact of the gender peculiarities over tuberculosis features and treatment outcome in the Chisinau city. **Material and methods:** A retrospective, selective, descriptive study targeting social, demographic, economic and epidemiological peculiarities, case-management, radiological aspects and microbiological characteristics of 467 patients registered with tuberculosis in the Chisinau city, the Republic of Moldova (MD) during 1.1.2015-31.12.2015 was performed. **Results**: the distribution based on gender identified the predominance of men 285 (61.03%) compared to women 182 (38.9%). Women statistically predominated in the group of 18-34 years old and men in the group of 35-54 years old. Every tenth patient from both groups was a hard-to-reach case. The microbiological positive cases constituted one third of both groups and multidrug resistance was identified in every tenth patient. Pulmonary infiltrative tuberculosis was diagnosed in most of the patients while severe forms such as disseminated, generalized and fibro-cavernous tuberculosis - more frequently in men. TB-HIV co-infection was established in a similar proportion in both groups. Social-vulnerable patients, from high risk groups, with associated diseases were identified at a similar rate in both groups. Treatment success rate was higher in women and lower in men. **Conclusions:** Women aged 18-34 years and men aged 35-54 years should be included in high risk groups for annual screening. Despite the lack of differences in the microbiological patterns severe forms such as disseminated, generalized and fibro-cavernous tuberculosis were more frequently diagnosed in men and as a consequence the treatment success was low. **Keywords**: TUBERCULOSIS, GENDER, SECTIONAL STUDY.

Tuberculosis (TB) represents a social disease (1, 2, 3, 4). It is the consequence of gross defects in social organization and errors in individual behavior (1). WHO placed the Republic of Moldova (MD) in the list of high burden countries for TB in the post-2015 era (3, 4). Social determinants that are increasing the susceptibility for tuberculosis are: poverty, low level of education, gender inequality, rapid urbanization, overcrowding, migration, malnutrition, smoking, alcoholism, HIV-infection and male sex (5, 6, 7). The relationship between male sex and tuberculosis risk is under-recognized due to highly complex range of factors (6, 7). These was identified a strong relation between notification rates, prevalence, mortality and male sex due to behavioral and physiological differences between men and women (7, 8). Although

epidemiological factors are important for spreading of the disease among men, specific issues that contributed to the increased risk of low treatment outcomes are underrecognized.

The aim of the study was to assess the impact of gender differences on the tuberculosis features in patients from the Chisinau city. The objectives were: 1. Assessment of the main epidemiological indices in the Chisinau city. 2. Assessment of general, socioeconomic and epidemiological risk factors of tuberculosis patients by gender distribution. 3. Evaluation of case-management, diagnosis, radiological aspects and microbiological characteristics of patients according to the gender distribution.

MATERIAL AND METHODS

There was performed a retrospective selective, descriptive study targeting social, demographic, economic and epidemiological peculiarities, case-management, radiological aspects and microbiological characteristics of 467 patients. The study included the patients registered in the Chisinau city (MD) in the period 1.1.2014-31.12.2014 as new tuberculosis cases. Inclusion criteria were: age > 18 years old, new case of tuberculosis and signed informed consent. Patients were managed in the clinical subdivisions of the Clinical Municipal Hospital of Phtysiopneumology of the Chisinau city according to the National Clinical Protocol. As a rule, the patients suspected with tuberculosis are investigated using the microscopic and bacteriological methods. Two smear samples are investigated after the staining by the Ziehl-Neelsen method and examined using the optical microscopy. Positive smears for acid-fast-bacilli are graded as 1+, 2+ and 3+. After the decontamination with N-acetyl-L-cysteine sodium hydroxide the sputum sample is inoculated on two slopes of solid medium Lowenstein Jensen. The slopes are incubated at 37°C and examined weekly for evidence of growth of colonies till 8 weeks. The growth was graded according to the number of the colonies. The drug susceptibility testing is performed for identification of the resistance against the first line antituberculotic drugs: isoniazid, rifampicin, ethambutol and streptomycin using the absolute concentration method on Lowenstein Jensen medium. The liquid culture methods, such as MGIT (Becton Dickinson), MB/BacT (BioMerieux) or Bactec 460 TB are compulsory used for testing the sputum samples of patients suspected with tuberculosis in association with solid Lowenstein Jensen medium. It confirms that tuberculosis in less than two weeks and drug susceptibility test for first-line drugs are obtained in the following two weeks. Additionally, the radiological examination is performed in all suspected with tuberculosis patients. Statistical analysis was carried out using the quantitative and qualitative research methods. For the comparative epidemiological assessment of major epidemiological indices in MD and Chisinau there were used the published data by the National Statistical Bureau and the National Centre for the Health Management (1).

RESULTS

According to the published data by the Moldovan National Centre for the Health Management in the period 2013-2015 there was registered an important decline of all epidemiological indices (1). The global incidence - which included new and relapsed cases) in MD decreased by 21.9% between 2013 and 2015 and by 22.1% - in Chisinau. A similar vector was established in respect of tuberculosis prevalence which decreased between 2013-2015 by 26.3% in MD and by 25.5% - in Chisinau. Less evidently decreased the incidence of new cases by 18.4% in MD and by 18.2% - in Chisinau. During the studied period the mortality decreased from 11.3 to 10.0 / 100,000 population in

MD, and from 10.8 to 6.9 / 100,000 population in Chisinau (1). The men and women ratio among new cases remains at the same level in MD and Chisinau demonstrating that men were two times more affected than women (tab. I).

In 2014, in the Clinical Municipal Hospital of Phtysiopneumology of Chisinau 467 cases were managed. The distribution according to gender identified the predominance of men 285 (61%) compared to women 182 (39%), $p<0.0001$. The male-female ratio was 1.56:1. The distribution by age groups identified the predominance of women in the 18-34 years old group and men in the 35-54 years old group. Distribution according to the demographic characteristics identified that two third of both groups were residents of urban districts of Chisinau. The patients from hard-to-reach groups that included citizens with lack of residence card, homeless or migrants were every tenth patients of both groups (tab. II).

By assessing the microbiological characteristics of the selected patients, it was established that the molecular genetic test GeneXpert MTB/Rifampicin contributed to the diagnosis of tuberculosis in most of the patients from both groups. GeneXpert MTB/Rifampicin resistant strains of *Mycobacteria* were identified in a similar rate of both groups. Smear microscopy identified a similar rate of microscopic positive results for acid-fast-bacilli in men and women groups. A similar rate of patients from both groups had culture positive results. Drug susceptibility testing on Lowenstein-Jensen solid either liquid (BACTEC MGIT 960 system) medium identified a higher rate of multidrug-resistant than mono- and poly-resistant strains of *Mycobacteria* in both groups (tab. III).

TABLE II

Distribution by demographic data

Indices	Age Residence	No. of cases 467		p value
		Men N=285 n (%)	Women N=182 n (%)	
Age groups	18-34 years	102 (35.79)	97 (53.29)	**<0.001**
	35-54 years	126 (44.11)	53 (29.12)	**<0.01**
	>55 years	57 (20.00)	32 (17.58)	>0.05
Residence	Urban	210 (73.68)	142(78.02)	>0.05
	Rural	75 (26.32)	40(21.98)	>0.05
Other categories	Lack of residence card	24 (8.42)	21(11.54)	>0.05
	Homeless	22 (7.72)	8(4.49)	>0.05
	Labor migrants	28 (9.82)	12(6.59)	>0.05

Note: Applied statistical test: paired simple T-test.

TABLE III

Distribution of patients by microbiological features

Characteristics		No. of cases 467		P value
		Men N=285 n (%)	Women N=182 n (%)	
Microbiological results	GeneXpert MTB/ Rifampicin positive	124 (43.5)	69 (37.9)	>0.05
	GeneXpert MTB/Rifampicin resistant	33(11.6)	27 (14.8)	>0.05
	Microscopic positive	80 (28.1)	45(24.7)	>0.05
	Culture positive	93 (32.6)	48(26.4)	>0.05
Resistance type at DST	Mono-resistance	4 (1.4)	1(0.54)	>0.05
	Poly-resistance	2 (0.7)	3 (1.7)	>0.05
	MDR-TB	31 (10.9)	20 (10.9)	>0.05

Note: Applied statistical test: paired simple T-test, DST-drug susceptibility testing. MDR-TB multidrug-resistant tuberculosis.

By assessing the case-management it was identified that the general practitioners detected more frequently men-187 (65.61%) comparing with women - 99 (54.39%). High risk groups screening was used more frequently for the detection of women 114 patients (40.00%) than of men-107 patients (58.79%). Addressed directly to the specialized clinical services were more frequently men (tab. IV).

By assessing the clinical radiological forms of tuberculosis, it was established that pulmonary infiltrative tuberculosis was diagnosed in most of the patients. Disseminated tuberculosis, generalized tuberculosis, lung destructions and involvement of both lungs predominated in men. A similar rate of extra-pulmonary tuberculosis was identified in both groups. The most frequently were diagnosed tuberculosis pleurisy and intrathoracic tuberculosis. TB-HIV co-infection was diagnosed in a similar proportion in both groups 16 (5.6%) cases in men and 10 (5.5%) cases in women) (tab. V).

When distributing the patients according to the economic status, it was established that women were more frequently employed and had health insurance policy. Students statistically predominated in the group of women due to a higher rate of early adult-

hood (ages 18-35) cases. Disease disabled were more frequently men, but women were more frequently retired. From infectious clusters there were more frequently women, but the statistical threshold was not achieved. Co-morbid status of TB patients was identified in a similar rate in both groups, as well as HIV-infection (tab. VI).

Treatment outcomes were assessed using the standardized indices. The highest success rate was established in the women group and the rate of patients with low treatment outcomes was higher in the men group. The low outcomes included: dead, failed and lost to follow-up patients represented 50 (17.5%) men and 12 (6.6%) women. Still continuing the treatment were patients treated according to the DOTS-Plus regimen for multidrug-resistant tuberculosis (tab. VII).

TABLE IV

Case-management and case-detection ways

Health level	Detection ways	No. of cases 467		p value
		Men N=285 n (%)	Women N=182 n (%)	
PHC	Detected by GPs-symptomatic	99 (34.7)	29(15.9)	>0.05
	Detected by GPs – screening of HRG	88 (30.9)	70(38.5)	>0.05
Ambulatory specialized level	Detected by SP-symptomatic	27 (9.5)	28(15.5)	>0.05
	Detected by SP-screening of HRG	26 (9.1)	37(20.3)	>0.05
Hospital	Direct addressing	45 (15.8)	18(9.9)	>0.05

Note: Applied statistical test: paired simple T-test. GPs-general practitioners, HRG- high risk groups.

TABLE V

Radiological characteristics of Moldovan TB patients

Parameters	Types	No. of cases 467		p value
		Men N=285 n (%)	Women N=182 n (%)

DISCUSSION

The actual study established an important decline of the epidemiological indices in the Republic of Moldova as well as in Chisinau. There are a lot of causes that determined this statistical improvement of the epidemiological situation, such as: low rate of high risks groups investigated in the frame of the active way of screening (annual chest radiological examination), high rate of migrants that are inaccessible for screening procedures, poor health care seeking behavior of the high risk groups and low accessibility to health care services of social vulnerable patients (7). Globally, men were more frequently diagnosed with tuberculosis than women with a male-to-female ratio 1.6:1 (4). Differences in active tuberculosis, according to gender sex distribution represented an important problem considering the high rate of men established in our research as well as in other studies (6, 7, 8). Multiple

gender-related factors that depend on regions were studied. In South Asia tuberculosis affected predominantly young women due to the high rate of the TB-HIV coinfection and pregnancy-related conditions (8). In our study, we also confirmed the predominance of young aged women and middle-aged men. A randomized meta-analysis of 3.1 million patients with tuberculosis from 28 countries established that men were more frequently microbiologically positive that were associated with social disadvantage in screening for detection and ensuring gender equity in health care (6). The most prevalent risk factors were established: alcohol abuse, imprisonment, drug use and associated diseases, such as chronic obstructive pulmonary disease, HIV infection and previous anti-tuberculosis treatment (6). The social and economic vulnerability was linked with the male sex in our research, as well as in a large number of international studies (5, 6, 7). Eastern Europe and Eurasia regions are confronted with numerous high risks, all being similar with those identified in our study: socioeconomic vulnerability, migration, detention, chronic alcoholism and therapeutic incompliance more expressed in the treatment of MDR-TB patients (4, 5, 6, 7, 9, 10). Connected to the detection and microbiological diagnosis, our study, as well as some foreign studies registered a low level of microbiological positive cases (5, 6, 7, 8). It could be explained by the low quality of the specimen collection procedure, disease-related factors and the low quality of the screening (11). One of the prevalent gender differences was higher rate of death in men comparing to women, however the statistical threshold was not achieved. The biological differences predisposed to a higher treatment outcome in the women group, without achieving the statistical threshold (8). Cigarette smoking was established as a high-risk factor for tuberculosis in the population of men from the Northern California (12). A cohort study conducted in Portugal for 4 years established that the male-female ratio was 2.1. The most affected age group in men was 40-49 years old and in women of 20-29 years age group. However, in the 50-59 years old group the male-to-female ratio constituted 3.4 (13). Conforming to the Czech health statistics the male-female ratio was 2.3:1 in the general population. According to the prevalence the most affected age group was constituted from patients aged more than 80 years old (14). Epidemiological data offered by Poland established that the incidence in men was 2 times higher than in women and the highest difference between sex groups was identified in patients aged 50-59 years old (15). In Romania the male-to-female ratio was 2.2:1 in 2012, with the highest incidence in the group 45-64 years old (16). Considering all related information, we can conclude that our study obtained similar results with other researches from high tuberculosis burden and low- or middle-income countries. So, we confirm gender inequality in patients with tuberculosis due to biological, socioeconomic vulnerability and harmful habits which were more frequently in men population.

CONCLUSIONS

The profile of patients enrolled in our study demonstrated that TB was more frequently diagnosed in women in the early adulthood and in men in the period of middle adulthood, due to the high rate of risk factors.

Urban residents constituted two thirds of our selected samples due to overcrowding of Chisinau and to criteria of the patients' selection.

Smear positive state as the criteria of the epidemiological danger was identified in every third patient and multidrug resistance

was identified in every tenth patient, demonstrating the tense epidemiological situation in Chisinau.

Men were more frequently detected as symptomatic patients and women - by high risk group screening. Social-economical high-risk factors in men were those associated to unemployment and in women - student and retired person's status.

The history of detention was more frequently met in men and infectious contacts, as being the resident of a disease cluster, it was more frequently met in women. Severe forms: disseminated, generalized and fibrocavernous tuberculosis was established more frequently in men.

Treatment success rate was higher in women and low outcomes (death and lost to follow- up) was established more frequently in men.

The present study indicates that the evaluation of the risk factors in men and women is important for screening programs which target susceptible subpopulations and establish the recommendations for the subsequent follow-up.

EMBOLIC STROKE OF UNDETERMINED SOURCE–THE TOP OF AN ONGOING ICEBERG (Abstract): Even though the incidence of cerebrovascular disease has decreased worldwide, stroke remains an important epidemiological concern due to its still high mortality and morbidity rates. Approximately one third of ischemic strokes are of undetermined cause according to the TOAST classification. From these cryptogenic strokes, ESUS is a separate entity caused by an underlying embolic mechanism. ESUS usually affects younger men and the severity of focal deficits is comparable to those of large-artery atherosclerosis. The most frequent cause of this non-lacunar cryptogenic stroke is covert atrial fibrillation and other atrial dysrhythmias. The aim of the present study is to provide up to date information regarding diagnosis and management of ESUS. Even though the current standard of ESUS treatment remains antiplatelet drugs, ongoing clinical trials address the need for chronic oral anticoagulation. **Keywords:** ESUS, COVERT ATRIAL FIBRILLATION, ANTIPLATELETS, ANTICOAGULANTS.

Even though stroke remains worldwide one of the most important disorders in terms of incidence, prevalence, mortality and morbidity, in the past years there has been a positive epidemiological change in developed countries due to efficient implementing of specific pharmacological and nonpharmacological prophylactic measures. According to recent reports of the American Heart Association, the incidence of both de novo and recurrent stroke has a tendency of declining. Also, in the last decade, the overall death by stroke has significantly decreased to a point that stroke has become only the fifth cause of death in the United States (1). The reported prevalence of cerebrovascular disease is 794 of hundred thousand people (2).

In spite of these positive tendencies, stroke remains one of the major health problems, especially in developing countries where it is responsible with 75.2% of deaths and 81.0% of stroke-related disability adjusted life years lost (3).The difference in incidence, prevalence and mortality rates vary along with geographical and demographical characteristics of populations, including specific associations of cardiovascular risk factors. For instance, according to Cuciureanu *et al.* who studied

70 patients diagnosed with ischemic stroke with spontaneous hemorrhagic transformation, the pathogeny of stroke in this specific population relied on interaction between atrial fibrillation, high blood pressure and dyslipidemia (4).

It is a general accepted fact that ischemic strokes represent the majority, comprising of approximately 87% of all strokes. These are followed by primary hemorrhages in a percent varying from 10% to 25%, with the highest prevalence among populations with Asian, Latin American and African descent compared to European descent (5). Only 3% to 5% of acute cerebrovascular disease is represented by subarachnoid hemorrhages (6).

Ischemic stroke, this black mark in the mortality and morbidity of cerebrovascular diseases, has been the focus of study throughout decades in terms of pathology, pathogeny, management and prophylaxis. Regarding etiology, nowadays more than 100 causes are known to be involved in its pathogenesis (7). In order to provide a much more accurate etiology and therefore a more efficient management, several classifications of ischemic stroke have emerged. These tend to be either phenotypic or causative. In the first category several classifications are included such as Baltimore-Washington or Causative Classification of Stroke System (CCS) (8, 9). All these phenotypic classifications grade the probability of every possible stroke etiology and, therefore, their main disadvantage is the lack of explicitly stating the most probable cause of stroke. On the other hand, causative ischemic stroke classifications use generally accepted inclusion criteria in order to segregate patients in specific etiological subgroups.

One of the most widely used causative classifications of ischemic stroke is the Trial of Org 10172 in Acute Stroke Treatment (TOAST) classification which divides ischemic stroke into five etiological subtypes: large-artery atherosclerosis, cardio embolism, small-vessel occlusion, stroke of other-determined etiology and stroke of undetermined etiology (10). According to Adams *et al*., the last category, also known as a cryptogenic stroke, is defined by impossibility of stating the etiology of the stroke. This occurs either despite extensive paraclinical examinations or in cases of scarce evaluation, or when at least two potential causes are discovered but the physician cannot point towards a single one (10). When using TOAST criteria, cryptogenic stroke seems to affect approximately one third of the elderly patients and up to 62.4% of young patients aged 15 to 45 years (11, 12). The incidence of cryptogenic stroke varies also with the inclusion criteria used in different classifications. For instance, the newer and improved version of the TOAST classification, the Stop-Stroke-Study TOAST (SSS-TOAST) classification which provides newer epidemiological and neuroimaging criteria has managed to decrease the incidence of cryptogenic stroke to 4 % when applied (13).

Starting from the general known fact that most non-lacunar ischemic strokes are embolic and from the observation that patients diagnosed with cryptogenic stroke have embolic pattern brain imaging, Hart *et al.* introduced the concept of embolic stroke of undetermined source (ESUS) which they defined as a cryptogenic stroke of thromboembolic nature (14). Thus, in 2014 a new stroke entity was recognized worldwide.

The importance of classifying a stroke as ESUS resides not only in lack of knowledge regarding recurrence rate but also in the management of this specific kind of stroke. Logically, if no cause of stroke is discovered then no proper secondary prevention treatment can be applied. Given these arguments, ESUS is one of the main focuses of the current studies worldwide, in terms of etiology, risk factors, recurrence predictors, extensive paraclinical evaluations and treatment. Therefore, the aim of the present review is to provide up to date information regarding diagnosis and management of ESUS.

ESUS DEFINITION, EPIDEMIOLOGY AND DIAGNOSIS

Despite intensive research towards etiology and management, a standardized definition of ESUS has not yet emerged. However, ESUS definition can be simplified to that of a subtype of cryptogenic stroke highly probable caused by an underlying embolic mechanism. If one takes into account its initial diagnosis criteria proposed by Hart *et al*, ESUS can be defined as a subtype of non-lacunar cryptogenic stroke characterized by absence of more than 50% occlusive atherosclerosis in arteries supplying the ischemic area, absence of major-risk cardioembolic source and absence of other specific stroke causes such as non-atherosclerotic arteritis, dissection or vasospasm (14).

Currently, there are scarce population-based studies regarding epidemiology, clinical and paraclinical characteristics and outcome of ESUS. According to the ESUS Global Registry study published in 2016, ESUS comprises of 16% of all ischemic strokes from the cross-sectional global sample of patients included (15). On the other hand, Ntaios *et al*. reported that ESUS represented 10% of ischemic stroke patients registered in the Athens Stroke registry between 1992 and 2011 (16). A major systematic review by Hart *et al* published in 2017 states that the average reported frequency of ESUS is 17%, in other words, one of every six strokes is of undetermined embolic source (17).

Even though incidence of ESUS may vary from one population to another due to several populational characteristics, there are some features that remain constant. For example, ESUS tends to appear at a younger age, with a mean age at presentation varying from 62 to 65 years compared to 68 years among non-ESUS cryptogenic stroke (15, 17). ESUS appears to affect men more than women, 58% compared to 42% (17). Patients with ESUS tend to experience symptoms at onset of low to moderate severity with a mean National Institute of Health Stroke Scale score of 5 (17). In other words, in terms of stroke severity, ESUS is reported to be similar to strokes due to large artery atherosclerosis and less severe than strokes caused by a major cardioembolic source (18).

Cryptogenic stroke is an exclusion diagnosis after extensive paraclinical evaluation. As new etiological and pathogenically theories emerge, several investigations can be added to the ongoing list. However, ESUS is diagnosis-criteria based and in accordance to the initial diagnosis criteria, in order to positively identify an ESUS, a minimum of tests must be performed: brain computer tomography (CT) or magnetic resonance imaging (MRI) that excludes lacunar infarcts, invasive or non-invasive imaging of extracranial and intracranial

arteries (catheter angiography or CT / MRI angiography or cervical duplex plus transcranial Doppler ultrasonography), 12-lead EKG, transthoracic echocardiography and minimum 24 hour cardiac monitoring with automated rhythm detection (14).Regarding brain imaging, in most countries, CT is the most used diagnosis tool in ischemic stroke unlike neurodegenerative disorders such as Parkinson's disease in which MRI is the adequate (19). In spite of this fact, recent studies reveal that contrast injected MRI is the golden standard in early diagnosing acute ischemic stroke, whereas use of certain contrast agents can point the real ischemic penumbra (20).

In addition to these basic investigations, recent studies concur that transesophageal echocardiography is mandatory in correctly diagnosing a cryptogenic stroke due to its superiority in analyzing aortic arch, left atrium and interatrial septum (11). Even though in their initial assessment, Hart *et al* did not recommend systematic proximal aortic arch imaging, a recently published multicentric study which assessed 677 cryptogenic stroke patients by using transesophageal echocardiography concluded that aortic arch plaque larger than 4mm, with ulcerative or mobile components increases the risk of ESUS (21).

Regarding detection of minor-risk potential cardioembolic sources such as covert paroxysmal atrial fibrillation or other atrial dysrhythmias, the role of prolonged cardiac rhythm monitoring is currently debated. The American Stroke Association recommends in its guidelines a 30 days prolonged cardiac monitoring in cryptogenic strokes whereas, European Society of Cardiology recommends a minimum 72 hours monitoring in all strokes with the possibility of exceeding this duration (22, 23). In the last decade a series of clinical trials have focused on the role of prolonged cardiac rhythm monitoring in diagnosing cryptogenic stroke and ESUS. The overall conclusion is that the longer the monitoring the higher are the chances to diagnose a paroxysmal atrial dysrhythmia. For instance, a study conducted on 441 cryptogenic stroke patients revealed that after a cryptogenic stroke, the use of an implantable monitoring device increases the rate of atrial fibrillation detection at 6 months to 8.9% compared to 1.4% by conventional management (24).

Several biomarkers are starting to be followed in several west-European countries in order to predict the presence of covert atrial fibrillation. Elevated levels of either atrial natriuretic peptide, brain natriuretic peptide and D-dimmersare predictors for asymptomatic atrial fibrillation (25).

ESUS – ETHIOPATHOGENY

ESUS patients appear to have fewer cardiovascular risk factors compared to non-cryptogenic stroke patients, from which hypertension, diabetes and previous stroke are in the top 3 (15, 25). ESUS is caused by several conditions which favor the formation of brain emboli. The most frequent source of emboli appears to be the heart in accordance to several studies which analyzed thrombus composition obtained from patients suffering from various types of ischemic stroke. The general conclusion was that the histology of thrombi is remarkably similar among cryptogenic strokes and cardioembolic ones, with higher proportions of fibrin, leucocytes and lower number of erythrocytes (26).

According to several trials dedicated to

prolonged heart rhythm monitoring, the most prevalent diagnosed cause after recurrence of non-lacunar ischemic stroke or during follow up is atrial fibrillation (24, 27). Das *et al.* who documented risk factors associated with silent cerebral infarcts in an updated sample of Framingham cohort showed that atrial fibrillation is significantly associated with silent stroke with an odds ratio of 2.16 (28). In less than 40% of ESUS cases atrial fibrillation is eventually detected.

Hence, new cardioembolic sources emerge, as covert atrial fibrillation and atrial high-rate episodes. An asymptomatic atrial high-rate episode is defined by an atrial heart rate of minimum 190 beats per minute with no clinical expression. Covert or subclinical atrial fibrillation is defined as atrial high-rate episodes lasting more than 6 minutes but less than 24 hours which have no clinical expression and are therefore detected only fortunately during continuous EKG monitoring (25). According to ASSERT study which followed 2780 patients with either pacemaker or implantable defibrillator, detection of atrial high-rate episodes lasting minimum 6 minutes is associated with an increased risk of developing atrial fibrillation and cryptogenic stroke (29). However, the causative and temporal relationship between atrial high-rate episodes and thromboembolic events has not been totally elucidated yet. Currently, it is not known whether atrial-high rate episodes and covert atrial fibrillation are certain causes of ESUS or simply markers of high thromboembolic risk (25).

A recent model was proposed for explaining the complex bidirectional relation between atrial fibrillation and ischemic stroke including ESUS. According to this model, systemic vascular risk factors induce in time an atrial cardiopathy that can manifest through atrial fibrillation which, in turn, will further cause remodeling of the atrium and worsen the cardiopathy (30). An ischemic stroke of any etiology can cause an autonomic malfunction including cardiac dysrhythmias by affecting certain autonomic regions of the brain. For example, it has been demonstrated that in right-handed patients, right middle cerebral artery infarction is associated with elevated heart rate while left middle cerebral artery infarction is associated with an enhanced parasympathetic control of the heart rate (31, 32). All these autonomic changes induced by ischemic stroke will aggravate the left cardiac disfunction (30). In resume, a vicious heart-brain-heart circle emerges.

More recent population-based studies have questioned the heart as the primary source of brain emboli in ESUS and placed nonstenotic, but potentially vulnerable atherosclerotic plaques situated in the carotid system or the aortic arch. Emerging data have shown that CHADS2 and CHA2DS2-VASc scores allow stratification of the risk of stroke recurrence and death in ESUS in association not only to atrial fibrillation in all of its forms but also in atherosclerotic plaques of the aortic arch. Specifically, aortic arch plaque larger than 4mm, with ulcerative or mobile components associate with a CHA2DS2-VASc score of minimum 2. However, so far, the associations of underlying embologenic diseases in ESUS with CHADS2 and CHA2DS2-VASc scores have remained essentially unknown (21).

According to the ESUS Global Registry, only 35% of patients had at least one minor-risk potential embolic sources and

no carotid artery plaques whereas, the majority of 79% of patients had no stenotic plaques in the cervical carotid arteries (15). These data suggest that the classical stenosis measurements which divide stroke risk and guide primary and secondary prevention of stroke are insufficient. Developments in plaque imaging investigations such as ultrasonography with and without contrast medium, micro emboli signal detection and 18Fluorodeoxyglucose positron emission tomography have discovered new high-risk plaque features. Among the latter, the most relevant are intraplaque hemorrhage, plaque ulceration, plaque neovascularization, fibrous cap thickness, the presence of a lipid-rich necrotic core, and evaluation of plaque inflammatory activity (33). Several small studies have proposed certain nonstenotic carotid artery aortic plaques complication as potential candidates but there remains an uncertainty whether these plaques are the cause of ipsilateral ischemic strokes (34).

In the case of paradoxical embolism as another brain emboli mechanism, potential sources are represented by the venous system in correlation with a patient with *foramen ovale* or *atrial septum* defect. Also, the existence of a pulmonary arterio-venous fistula can be a rare cause of ESUS (14). One must also not forget tumor emboli from unknown cancer or even marantic endocarditis (14).

ESUS-TREATMENT

The intense research regarding causes and mechanisms of ESUS is justified by the imperious need of implementing clear secondary prevention treatment guidelines. Even though the existence of brain emboli which defines ESUS is a clear indication for anticoagulants, in the absence of demonstrating the actual source of emboli, most physicians treat ESUS with antiplatelet drugs. According to Hart, 86% of ESUS were treated with antiplatelet therapy and the average annualized rate of recurrence was quite elevated, at 4.5% (17). These data point towards use of oral anticoagulants in the secondary prevention of ESUS.

Three recent trials evaluated the use of novel oral anticoagulants in the prevention of recurrent ESUS (34, 35, 36). From these, RE-SPECT ESUS was a multicenter randomized double-blind phase III trial which compared the effects of dabigatran twice daily with aspirin once daily in terms of ESUS recurrence and major bleeding in two equal lots which had a median follow-up of 19 moths (35). Even though dabigatran in any of the two generally available dosages did not associate with higher major bleeding events, there was no statically significant differences regarding stroke recurrence between this direct oral anticoagulant and aspirin. However, more no major bleeding events associated more frequently with dabigatran when compared to aspirin. NAVIGATE ESUS was also a multicenter randomized double-blind phase III trial which instead compared the effects of rivaroxaban 15 mg daily with aspirin once daily in terms of ischemic/hemorrhagic stroke or systemic-embolism recurrence and major bleeding in two equal lots which had a median follow-up of 11 moths (35). The results revealed that not only rivaroxaban is not superior to aspirin in stroke prevention but also is associates with a higher risk of bleeding (34). ATTICUS is an ongoing multicenter randomized double-blind phase III trial which compares the effects of apixaban versus aspirin once daily ad-

ministered in ESUS patients in terms of ESUS recurrence (36). The first two trials are comparable in terms of lot dimensions and time interval follow-up and they both conclude in favor of antiplatelet treatment. The third study, however, is using much smaller lots due to the fact that one of the mandatory inclusion criteria is represented by the already existence or the planned implantation of an insertable cardiac monitor. Therefore, the aim of the ATTICUS study is not only to compare effectiveness of apixaban versus aspirin but also to investigate the impact of atrial fibrillation (36).

ESUS-A GLIMPSE OF THE FUTURE

As advances in technologies occur, new diagnosis criteria will add to the list of ESUS. For instances, advanced imaging of carotid aortic plaque such as MRI and 3d ultrasound are currently used in certain laboratories. 3D ultrasound is superior to Doppler ultrasound in terms of image quality and accuracy, with an increased rate of small ulceration detection (12).

One of the current concerns in terms of ESUS is to determine new clinical, biological and cardiological predictors for primary diagnosis or recurrence in order to prevent these events. Apparently, ischemic stroke recurrence after ESUS is corelated with high values of nontraditional lipid parameters such as total cholesterol/high density lipoprotein-cholesterol and low-density lipoprotein-cholesterol/ high density lipoprotein -cholesterol ratios (37). According to Chung *et al.* who measured the levels of plasma free fatty acids during the acute phase of ESUS or cardioembolic stroke in 254 patients, high levels of free fatty acids associate with more severe focal deficits at onset, increased volume of the ischemic lesion and increased prevalence of large cortical infarcts. Therefore, one possible way to reduce ischemic lesion volume and clinical severity is to lower the plasma level of free fatty acids (38).

Meisel *et al.* who studied the shape and function of the left atrium in18 ESUS patients discovered that the left atrium has both at rest and exercise dysfunction due most likely to a spherical remodeling (39). Thus, one possible way to identify high risk-ESUS patients is to analyze the left atrium and to determine certain at rest and during exercise functional parameters such as end-diastolic volume and dejection fraction.

Unfortunately, diagnosis of subclinical atrial fibrillation in stroke patients remains a challenge for most clinicians. One direction, as stated previously, is to increase as much as possible the duration of cardiac rhythm monitoring. Other modalities are following certain EKG parameters such as P wave dispersion, P wave duration and PR interval duration's wave dispersion is defined as the difference between the maximum and the minimum P wave duration detected in a 12-lead ECG and it is a known predictor for atrial fibrillation (40). P wave dispersion, PR interval longer than 200 ms and a P wave duration over 120 ms reflect atrial disfunction secondary to atrial remodeling which can be a cause for atrial fibrillation (40). Regarding biological markers of atrial fibrillation, according to Acampa *et al.* inflammatory markers such as high-sensitive C-reactive protein are related to presence and persistence of atrial fibrillation and, therefore, can be used as suggestive parameters in ESUS patients (41). In order to even better individualize

ischemic strokes caused by emboli formed in the heart secondary to yet undetected atrial fibrillation, a new stroke category recently emerged, SURF or Stroke with Underlying Risk of Atrial Fibrillation (42).

CONCLUSIONS

ESUS is a quite novel entity with important implications in its management. Although its main defining criteria are established since 2014, new paraclinical criteria emerge as new potential causes and mechanisms are discovered. Future studies are required in order to identify new etiologist – potential targets for specific prophylactic treatments.

Despite high prevalence of covert atrial fibrillation and other high risk atrial tachyarrhythmias, the current standard of ESUS treatment remains antiplatelet drugs.

LUTEOLIN, A FLAVONOID AS AN ANTICANCER AGENT

Diet and consumption of bioactive compounds from natural sources (fruits and vegetables)have been recognized for their preventive role against a variety of human diseases including cancer. The inhibitory effects of phytochemicals found in plants against major diseases are well documented in literature. In this context, luteolin, a flavonoid found in different fruits and vegetables has been known as an anticancer agent through inducing apoptosis and cell cycle arrest and trough inhibiting metastasis and angiogenesis in multiple cancer cell lines such as breast, colon, pancreatic among other. Luteolin can be an important complementary medicine for the prevention and treatment of different types of cancers, owing to its natural origin safety and low cost relative to synthetic cancer drugs. However, since most of the findings are based on in vitro and vivo studies, which do not necessarily represent the effect on humans, more work on different pharmacokinetic parameters and may involve human subjects is needed in the future before this substance becomes a prescribed drug. Luteolin (3,4,5,7 tethrahidroxi flavone) is an natural flavonoid, extensively present in many plant species. It is particularly present in fruits and vegetables such as celery, chrysanthemum flowers, sweet bell pepper, carrots, onion leaves, broccoli and parsley (Muhammad Imran, Abdur Rauf, Tareq Abu-Izneid, Muhammad Nadeem, Mohammad Ali Shariati, Imtiaz Ali Khan, Ali Imran, Ilkay Erdogan Orhan, Muhammad Rizwan, Muhammad Atif, Tanweer Aslam Gondal, Mohammad S. Mubarak, *Biomedicine & Pharmacotherapy*, April 2019,Volume 112).

EDITORIAL

ESTABLISHMENT AND CONSOLIDATION OF THE SUPERIOR MEDICAL EDUCATION SCHOOL IN IAȘI. ROLE OF THE SOCIETY OF PHYSICIANS AND NATURALISTS OF IAȘI

1830-1833: ***The Society of Physicians and Naturalists of Iași, a ferment of Moldavian medical education***. Designed on January 11th, 1830, in the form of a *Medical Reading Circle* within the *Spiridonia* Hospital, and having the representatives of the Doctoral Council in the capital of Moldavia among its first members, the Society of Physicians and Naturalists of Iasi (SMN) was fully recognized on March 18th, 1833. Its founders were doctors Iacob Cihac, the city's chief obstetrician, with a doctorate at Heidelberg, and Moldavia's protomedicus, Mihail Zotta, with a doctorate in Vienna, the first Romanian licensed physician in Bucovina. As an association of academic type, SMN was the first scientific society in the Romanian Lands, and in South-East Europe as well. It gathered not only doctors and pharmacists from all over the Principality, but the intellectual, political and religious elite of the country, of neighboring regions inhabited by Romanians, along with many outstanding scholars from different European countries. Almost all the founders of the Iasi medical school were SMN members and/or leaders, benefiting from what that Little Academy had founded in national première: the Library (1830), the Museum (1834), the Botanical Garden (1856), all of public use. Against the background of emulation that the introduction of the Organic Law (1832) and the 1848 Revolution in Moldavia aroused, things finally started moving in this forgotten corner of the world, also due to the particularly rich scientific and cultural life SMN generated. Concurrently, this context facilitated the founding of the Michaelian Academy (1835), the University (1860) and finally, the Faculty of Medicine (1879). Iacob Cihac, the author, in 1837, of the first treatise on natural history published in Romanian at the *Albina Institute* in Iasi, delivered a Natural History course at the Michaelian Academy. Dreaming of a Faculty of Medicine, in his speech at the Congress of the Naturalists in Freiburg in 1838, he already talked about the "the hope of opening a course of surgery in Iasi". His initiative was going to become true only after the "By-laws for the reorganization of public education.." were enacted in 1851, and especially after the 1859 Union (1).

1852-1864: The premise of higher medical education in Iasi. In the second half of the XIX-th century, the process of medicalization of the society and professionalization of health care institutions was intensified in the Romanian Countries as well. Following the promulgation in 1851, by the Prince Grigore Alexandru Ghica, SMN president in 1834, of the document "By-laws for the reorganization of public education in the Principality of Moldavia", the establishment within the Michaelian Academy of a Medicine Faculty was considered, however, a process that had to be prepared by taking intermediate steps, because "the means and the needs of the country do not allow the immediate creation of a Medi-

cal Faculty". Thus, in this Province, too, similarly to Muntenia, a School of Midwifery – *The Gregorian Institute*, in 1852, and two *Schools of Surgery*, one in 1859 and another in 1863, were established in the beginning. These preliminary structures, of secondary medical instruction, owed much to the efforts made by Dr. Gheorghe Cuciureanu (Cuciuran), protomedic of Moldavia during the years when the Gregorian Institute was designed, and by Dr. Anastasie Fătu, chief doctor, first manager and professor, animator and tutor of the Institute, and by Dr. Neculai Negură, a close friend of Cuza Vodă, and Dr. Ludovic Russ senior, for the surgical art, respectively. (2) In fact, Dr. Negură, a SMN member after 1862, submitted in October 1859 to the Ministry of Cults and Public Instruction the *Statutes of the Medical Faculty to be created in Iasi*. On December 3rd, 1859, he obtained, by a princely ordinance issued by Alexandru Ioan Cuza, the right to open a *School of Surgery* at the Michaelian Academy. Nicolae Negură's S*chool of Surgery and Medicine* (November 30th, 1859-1861) included the *Surgery Course* of this enthusiastic initiator, together with a *Pharmacy Course*, held by the pharmacist Iosif Mihailovici. Both courses were free and benevolently offered to the participants. The *Course of Surgery* dealt with notions of Anatomy and Dissection, Principles of Physiology and Surgical Pathology (3). It was the first medical university course in Romanian (4). If Anastasie Fătu already wrote in 1852 a *Handbook for the teaching of midwives* (*Buciumul Român* Printing House, Iasi) and a *Handbook of Popular Practical Medicine* (*D. Gheorghiu* Printing House, Iasi, 1871), Dr. Negură only translated Josef Hyrtl's Anatomy, failing to publish it. From August 1st, 1863, Dr. Ludovic Russ senior, guardian of the SMN Museum and chief physician of the Surgery Section of the "St. Spiridon" Hospital, gave a free *Course of topographic anatomy, upper and operative surgery, bandages and instruments*, teaching 14 chapters. For this purpose, the "St. Spiridon" Hospital of Iasi, where Russ was chief medical officer of the Surgical Department, placed its clinical basis at his disposal. (5)

Meanwhile, in 1859, the School of the Sanitary Company opened its doors in Iași, due to Dr. Iacob Cihac, deputy protomedic of Moldavia and chief physician of the Moldavian army, the one who printed that very year (1859), in the *Bee* Printing House [Tipografia Albinei] of the reputed scholar Gheorghe Asachi, a *Handbook for teaching the soldiers of the sanitary company of the Moldavian-Romanian army*, the first medical-military book in the Romanian literature (6).

The first attempts to start pharmaceutical education in Iași date back to 1830, accompanying the organization of the Society of Physicians and Naturalists of Iasi (SMN), among whose members there were numerous chemists, pharmacists and doctors interested in characterizing and valorizing the flora, fauna and mineral resources of Moldavia. The fruits of these efforts were noticed only in 1857, when the Pharmaceutical Guild, - founded in the Moldavian capital in 1854, - set up the *Preparatory School of Pharmacy*, under the administration of Dr. Ludovic Steege, protomedic of Moldavia and Cuza's ally, and of the pharmacist Theofil Stenner. Intended for the apprentices in the last year of pharmaceutical practice, the School operated within the "St. Spiridon" Establishment, where, according to the Guild Statutes, a laboratory and a library were created. The teaching language was Romanian. The School of the Guild of

Pharmacists functioned from 1857 to 1859. Graduates were pharmacy assistants (7).

All these were precursory forms of higher medical education, expected to be implemented in Iasi once the conditions,- involving the degree of training of both masters and candidates, as well as the optimal spaces and equipment for the didactic process-, would be met. Thus, Romania was aiming at attaining Western-European standards, not risking to laurel second-hand doctors. The founding of the University of Iași, the first high-ranking academic forum in the Romanian Principalities, officially celebrated on October 26th, 1860, illustrated such a favorable circumstance. If, sacrificing itself on the altar of National Union in 1859, Iași had lost the status of Capital of the small country of Moldavia, it had instead to "become the seat of science, the focal point of Romanian intelligence", a capital of the nation's progress and culture, as Mihail Kogălniceanu emphasized, and as Prince Cuza wanted it to be, too. Both Kogălniceanu and Cuza, leading unionists closely linked to the life and role of the SMN, were directly involved in the attempt to establish the Faculty of Medicine in Iasi. On September 16th, 1860, during the meeting of the School Council – gathering the General Inspector of Schools, the Department Director, the Director of Education and three professors elected among the secondary and primary school teachers -, it was Dr. Iacob Cihac to read the *Programme of the Faculty of Medicine* that the Ministry of Public Instruction had sent (Statement No.10976). The Council decided that for that year, the Faculty of Medicine should appoint only professors of Theoretical Anatomy, Surgery and Pharmacy. For other medicine-related sciences, medical students had to attend the Faculty of Philosophy, section I (of sciences). (8) However this approach found no echo. It was a mere mirage: the project had to wait for other 19 years.

December 1, 1879: From fiction to university reality. Predicted *de jure* to exist first within the Michaelian Academy, inaugurated in 1835, then within the University of Iasi, opened in 1860, the Faculty of Medicine began its activity *de facto* only on December 1st, 1879, when the Parliament of the Kingdom of Romania voted the budget and the syllabus of the institution. The decree no. 11389 of September 27th, 1879 was signed by the Minister of Public Instruction of that time, Dr. Nicolae Kretzulescu, eminent surgeon, politician and patriot. The Faculty of Iași was particularly urged to train the local youth, who by their knowledge, dedication and devotion, had to face the severe medico-social problems that had always plagued the country.

The first professors of the Faculty of Medicine were substitutes, and in Iași the title of doctor of medicine and surgery could only be granted since 1887. The Ministry had accepted Dr. Leon Logothety Sculy, a skilled surgeon specialized in Paris, and a student of Ludovic Russ sr in Iasi, to teach Anatomy and Histology, whereas pharmacist Samuel Konya, doctor of the University of Vienna, a valuable SMN representative, a former student of the Michaelian Academy and of the School of the Iasi Guild of Pharmacists, was responsible for teaching Chemistry. (9) The Faculty was assigned two rooms in the University headquarters, which itself had an inadequate premises. At that moment (1875-1880), its rector was Prof. Dr. Petru Suciu, a lawyer. Without previous festivi-

ties, the courses started on December 1st, 1879. The inaugural lecture, that of Anatomy delivered by Prof. Dr. Sculy at only 26 years of age, in his position as the first dean (1879-1881) of the Faculty, addressed a number of only 14 students, registered in the Ist year. In the meantime, Dr. Konya was replaced by another famous SMN member, chemist Petru Poni, scientist of international notoriety, professor at the Faculty of Sciences of the Iasi University and academician. The newspapers of that time welcomed the event with great restraint, speaking of an "imaginary Faculty" (10).

If the SMN contributed to the establishment and consolidation of the Medical Faculty, the Faculty gave soon consistency to the first scientific periodical that the pioneering academic association ever edited: *The SMN Bulletin*, published in a bilingual edition - Romanian and French - on January 1st, 1887. It followed the SMN first short lived editorial attempts - *The Guide to Health and Economy. Leaflet for the Romanian people* (1844-1845) and *Leaflet of the Society of Physicians and Naturalists of the Principality of Moldavia* (1851-1853), publications disseminating sanitary education and domestic medicine. In 1924, *The SMN Bulletin* was renamed *The Medical-Surgical Journal. Bulletin of the Society of Physicians and Naturalists in Iași*, a title that it retained until today. *The Medical-Surgical Journal* was also the periodical of the Faculty of Medicine and of the Spiridonia Hospitals, as well as of the University of Iasi. But it was only when the university medical-pharmaceutical activity intensified that the SMN periodical could gain real value, surviving hard times. Now it is printed in English and is included in the Web of Science Core Collection - Clarivate Analytics. In 2019, this journal of the medical academic staff reached its 123rd volume.

Set up with huge difficulty 140 years ago, the Faculty of Medicine, cornerstone of higher medical education in Iasi, proved to be resilient and fertile, supporting the dynamic evolution of an ever more flourishing and fruitful *alma mater*.

The Tree of Medical Education in Iași at the present time

As a consequence of the Education Reform in 1948, the Faculty of Medicine separated from the University of Iasi and was transformed into an Institute of Medicine and Pharmacy, enjoying a much larger autonomy. Later, in 1991, the Institute turned into a University of Medicine and Pharmacy, placed under Professor Grigore T. Popa's protective genius.

The history of the three other Faculties the University includes today, besides the classic **Faculty of Medicine** – its nucleus, is also an interesting one.

The Faculty of Pharmacy. After 1879, the year when the Faculty of Medicine began its activity, the Professor Council insisted on the establishment of a *Pharmacy School*, too, starting even on October 1st, 1898 (11). The request was not accepted, although the pharmacists were extremely sought after, and their important role in the life of the society justified the existence of a specialized higher school. The attempt was repeated in 1908, when in the business meeting of February 29th, 1908, the University Senate unanimously admitted the establishment of a *School of Pharmacy* belonging to the Faculty of Medicine (12). The same failure occurred. Only between 1913-1934, a *Pharmacy Education Section*

could be attached to the Iași Faculty of Medicine. The section reopened between 1948-1952, whereas in 1965 it was resized as a Faculty of Pharmacy, which has brilliantly developed since then on. Prof. Dr. Gheorghe Popovici was its first dean.

The Faculty of Dental Medicine. Dental education could hardly find its way in Iași. Responding to the needs of medical-health care, immediately in the post-war period, in 1945, Dentistry was introduced as a compulsory study subject, in the form of a Conference / Chair / Section of the Faculty of Medicine. It was the first time that the medical students of Iasi learned the concepts of dental medicine. If between 1945-1946, it was a section of the Faculty of Medicine, in 1948 the Faculty of Stomatology was created, which resisted until 1952, when the difficulties related to specialized chairs forced the cessation of its activity. It was coordinated by a skilled surgeon, Prof. Dr. Nicolae Dutescu. On october 25th, 1965, the Faculty of Stomatology was reestablished, and after 1990, it was renamed the Faculty of Dental Medicine. Soon it imposed itself as a meritorious institution, which to this day has plenary contributed to the renown of university medical education in Iasi. Its first dean was Prof. Dr. Gheorghe Timoșca, a specialist in oro-maxillo-facial surgery (13).

The Faculty of Medical Bioengineering. Continuing the avant-garde initiatives of the Iasi medical school, along with SMN traditions that combined art, technique and science at all times, in 1994, within "Grigore T. Popa" University of Medicine and Pharmacy, the Faculty of Medical Bioengineering could be inaugurated, due to its first dean's efforts, Prof. dr. Florin Topoliceanu. Later the Specialization of *Balneophysiokinetotherapy and Rehabilitation*, with bachelor's studies, was equally added to its initial structure.

Visibility. Furthermore, the international recognition -that SMN and the Faculty of Medicine have always promoted- is currently completed, substantially improved and amplified by the study programmes in English and French languages and the Erasmus programmes that the University of Medicine and Pharmacy carries out, by the *Medical-Surgical Journal*, and many other international publications and collaboration agreements the University teaching staff is promoting.

On September 5th, 2017, "Grigore T. Popa" University of Medicine and Pharmacy became the first institution of higher medical education in Romania listed in the *Times Higher Education World University Rankings*. As to the international academic visibility indicator, it ranked first in Romania and among the first 500 universities in the world (428th place).Thus the successful beginnings have constantly represented prerequisites for future achievements, synchronizing "Grigore T. Popa" University to continually updated professional priorities. Now its overall academic activity undoubtedly illustrates the main development directions of globalized contemporary medicine.

On the other hand, due to the flourishing Faculties within the University of Medicine and Pharmacy, the SMN sections and activities have significantly grown. Moreover, while most of the SMN presidents have always been professors of the Faculty of Medicine, in recent years, rectors of the University of Medicine and Pharmacy have been elected SMN presidents, increasing the chances of coherent programmes, both institutions can undertake in partnership.

Here are the fruits borne over time by the fragile branches once visionary forerunners had sprouted with confidence and hope!

To them grateful thoughts are unfailingly addressed on each succeeding anniversary of those days.

NONCARDIAC CHEST PAIN AND GASTROESOPHAGEAL REFLUX DISEASE (Abstract): Gastroesophageal reflux disease (GERD) may manifest typically with heartburn and regurgitation or may have atypical manifestations as laryngitis, asthma, chronic cough or noncardiac chest pain (NCCP). While typical GERD is easy to be recognized, the atypical extraesophageal symptoms of the disease make the diagnosis difficult because most patients do not have heartburn or regurgitation. Most common atypical manifestations include ear, nose and throat (ENT), pulmonary or cardiac symptoms. GERD should be included in the differential diagnosis of patients with atypical symptoms, especially when alternative diagnoses are excluded. NCCP is defined as recurring angina-like substernal chest pain of noncardiac origin. We present the most recent epidemiologic data, path physiology, diagnosis and treatment of NCCP. The major causes of NCCP are GERD and esophageal dysmotility. By far, GERD has been demonstrated to be the most frequent source of NCCP. After a complete cardiac evaluation, the patient with NCCP will be referred to a gastroenterologist. All recent studies suggest the use of PPI test as the first diagnostic tool in patients with NCCP. The invasive diagnostic tests (especially, the 24-hour pH monitoring and esophageal manometry) are used only in those cases who do not respond to PPI therapy. Patients with GERD-related NCCP require long-term treatment with a PPI. **Key words**: GASTRO-ESOPHAGEAL REFLUX DISEASE, NONCARDIAC CHEST PAIN

CUT-OFF VALUES OF ANTHROPOMETRIC MEASUREMENTS, HANDGRIP STRENGTH, PHYSICAL ACTIVITY AND GERIATRIC SCORES FOR THE MALNUTRITION RISK AMONG OLDER PATIENTS WITH CHRONIC KIDNEY DISEASE

CUT-OFF VALUES OF ANTHROPOMETRIC MEASUREMENTS, HANDGRIP STRENGTH, PHYSICAL ACTIVITY AND GERIATRIC SCORES FOR THE MALNUTRITION RISK AMONG OLDER PATIENTS WITH CHRONIC KIDNEY DISEASE (Abstract): **The aim** of the study is to describe the prevalence of malnutrition and to determine the prognostic role of geriatric assessments and anthropometric measurements in patients with malnutrition. **Materials and methods**: Eighty patients with chronic kidney disease hospitalized in a geriatric clinic from north-eastern Romania were included. A geriatric evaluation was performed [Mini Nutritional Assessment-MNA, Geriatric Depression Scale-GDS, daily activities (Activities of Daily Living-ADL, Instrumental Activities of Daily Living-IADL), cognitive impairment scores (Mini-Mental State Examination-MMSE) and frailty (Fried criteria)]. We also evaluated muscle strength and calf/arm circumference. Using the area under the curve (ROC) analysis, cognitive status, depression, frailty, physical activity, handgrip strength and anthropometric measurements were evaluated as possible predictors for malnutrition. **Results**: MNA reported malnutrition in 8.75% of cases and 58.75% were at risk of malnutrition. ROC curve analysis showed that the arm and calf circumference predict nutritional status with very good accuracy, while muscle strength, GDS and Fried criteria have also good accuracy (specificity, sensitivity). **Conclusions**: Our research has found a strong correlation between nutritional status, anthropometric measurements, and handgrip strength. Malnutrition should be carefully evaluated in frail or depressed older patients with CKD. **Keywords:** MALNUTRITION, GERIATRIC EVALUATION, CHRONIC KIDNEY DISEASE, FRAILTY.

Chronic diseases and aging are major global public health problems correlated with increased life expectancy. One of the common disorders that appears with aging is chronic kidney disease (CKD). After the age of 30, glomerular filtration rate decreases progressively, Australian Diabetes, Obesity and Lifestyle Study (AusDiab) suggesting

that over one-third of people over 65 years-old have an estimated glomerular filtration rate below 60 mL/min/1.73 m² (1, 2). This population group is often at risk of frailty and malnutrition.

Food intake decreases with age. Older people tend to lose hunger sensation, eat smaller meals, have fewer snacks between meals and also eat slower (3). Most individuals lose weight, in varying proportions, as they age (4). Loss of muscle tissue is associated with decreased strength, bone mass and cognitive function, anemia, immune system dysfunction, slower recovery after surgery and, consequently, an increase in both morbidity and mortality (5). In addition to "aging anorexia", there are a multitude of physical, social, cultural, environmental, psychological and financial factors for an inadequate diet (6-8).

Often considered to be a late complication in CKD, malnutrition occurs from the early stages of kidney disease (9,10), with direct implications in the evolution of the disease.

The prevalence of malnutrition among older patients with CKD differs depending on the methods used (anthropometric parameters - arm circumference, tricipital fold, body mass index - biochemical or nutritional status assessment questionnaires), suggesting a wide variety of tests and methodology applied, with multiple predetermined cut-offs (11).

The problem of malnutrition is even more complex due to the heterogeneity of the geriatric population, with various symptoms, disorders and treatments that affect their nutritional status (12-14).

The ultimate goal is to improve the quality of life and ensure successful aging. In order to achieve this goal, the risk and predisposing factors leading to the development of malnutrition have to be recognized. As a result, both clinicians and researchers should explore the possible associations between nutritional status and various predictors and outcomes, to determine clear cut-offs.

In Romania, to date, there has been no estimation of the prevalence and even less of the incidence of malnutrition in older patients with CKD, making it more difficult to maintain a correct record of those who need an early therapeutic approach.

Our research aimed to study the interplay between nutritional status and the main components of the geriatric evaluation (cognitive status, depression, functional status, and frailty) and to establish the prognostic role of several assessments for patient's malnutrition status.

MATERIALS AND METHODS

Participants

The retrospective study included 80 patients (28 men and 52 women) admitted to a geriatric clinic from Iasi, Romania. Patients younger than 65 years old, with severe comorbidities (neoplasia, recent bone fractures), severe cognitive impairment, without CKD, or those who refused to participate in the study were excluded. In the remaining 80 patients, several measurements and scores were performed.

Demographic data and physical performance

Demographic data were obtained from the case history and the observation sheet. For the anthropometric measurements (arm/calf circumference) we used standard techniques and an electronic dynamometer was used to evaluate muscle strength. Physical function was assessed through the Short Physical Performance Battery

(SPPB) that combines the results of the gait speed, chair stand and balance tests. The scores range from 0 (worst performance) to 12 (best performance). The test has been shown to have predictive value showing the risk for disability, nursing home admission and mortality. The cut-off point we used for the statistical analysis was < 8 points.

Geriatric evaluation

Mini-Nutritional Assessment (MNA) was used as a screening tool to evaluate the nutritional status. Patients with a score between 24-30 points were considered well-nourished, those between 17-23.5 points were at risk of malnutrition and the older patients with a score bellow 17 points were considered malnourished. We also evaluated the cognitive status (by the Mini-Mental State Examination – MMSE) and the frailty syndrome (Fried criteria). The capacity of performing the activities of daily living was assessed through Activities of Daily Living (ADL) and Instrumental Activities of Daily Living (IADL) scores.

All the patients completed the questionnaires individually, to avoid the subjective factor. Signed informed consent was obtained from all the study participants before data collection.

Statistical analyses

Means, standard deviations and percentages were used for descriptive analysis. Comparative analysis was performed using Independent Samples t-test and One-way ANOVA. For correlational analyses we used Pearson and Spearman correlations. Cut-off value was determined between each anthropometrical index and geriatric evaluation parameters by the receiver operating characteristic (ROC) curve, which was quantified by the area under ROC curve (AUC). The Youden's index (sensitivity+specificity-1) was used to determine the optimal cut-off point of each index. P-value < 0.05 was considered to be statistically significant. Statistical analysis was performed using *SPSS Statistics version 21.0.*

RESULTS

Demographic data

The mean age was 76.74±5.93 years, higher among women (77.79±5.64 years versus 74.79±6.05 years, p=0,03). The prevalence of malnutrition was 8.75% (n=7) and 58.75% (n=47) were at risk. Women had a higher prevalence of malnutrition than men (tab. I).

Hypertension was the most prevalent comorbidity in our study group, followed by cardiac failure and diabetes mellitus. No statistical difference in demographic characteristics could be found between stages of malnutrition, except age (p=0.007).

Anthropometric measurements and physical activity

Patients with malnutrition had a smaller arm circumference (21.14 cm versus 28.19 cm in well-nourished patients, p=0.002) and a smaller calf circumference (29.29 cm versus 36.23 cm in well-nourished patients, p<0.001). Muscle strength was also decreased (tab. II).

Geriatric evaluation

A geriatric evaluation revealed that 36.25% had moderate cognitive impairment. All patients needed help (partially/totally) to carry out the activities of daily living. IADL was significantly lower in patients with malnutrition (p=0.01). Also, malnourished patients were more depressed and frailer (women more than men) (tab. III).

ROC curve

Anthropometric measurements, geriatric evaluation scores and physical performance were explored as possible predictors for malnutrition. Furthermore, to determine the cut-off point with optimal specificity and

sensitivity for each tool, we performed cut-off analysis (fig. 1, tab. IV).

Only arm (AUC = 0.832) and calf circumference (AUC = 0.842) had very good accuracy in identifying patients with malnutrition. A value < 23 points in the arm circumference offers 100% sensitivity and 61.64% specificity, while a value below 32 at the calf circumference offers 100% sensitivity and 60.27% specificity.

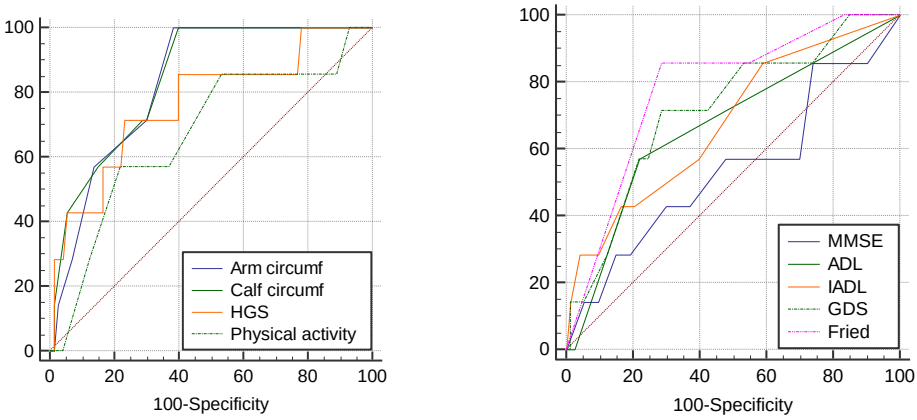

Fig. 1. ROC curves according to different cut-off values for arm circumference, calf circumference, handgrip strength and physical activity score.

Muscle strength, GDS and frailty score had also a good accuracy in identifying patients with malnutrition. Physical activity, cognitive status and the ability to perform the activities of daily living had no predictive power for malnutrition in our study group.

Linear correlations between geriatric evaluation scores and different demographics and anthropometric parameters are presented in Table V. Univariate correlations showed that only age and calf circumference have a significant correlation with MMSE ($p < 0.05$). MNA was significantly correlated with ADL, IADL and GDS.

TABLE IV

DISCUSSION

The assessment of nutritional status remains a challenge in medical practice. Although an essential part in the complete evaluation of older patients, it is often overlooked, clinicians focusing on other aspects. Malnutrition as an independent factor in the development of other disabilities, has a negative impact on the general health status and quality of life (15).

In our study, malnutrition was evaluated through the Mini Nutritional Assessment. 8.75% of the patients were malnourished, a lower number compared to other studies that showed different percentages in older patients with CKD, between 28-65%, depending on the criteria used for the diagnosis. Most of them included end-stage renal disease (ESRD) patients who were already on dialysis and only a few pre-dialysis patients (16, 17). However, 58.75% of our patients were considered to be "at risk", a very important aspect of our findings. Patients at risk of malnutrition have in most cases normal weight or are overweight, which is why they are often overlooked, and nutritional tests are not performed. The risk of developing malnutrition is high, with a significant impact (lower quality of life, increased risk of hospital admissions, higher mortality rates). Furthermore, this is the reversible stage of the disease, in which early intervention can change the overcome.

Malnutrition correlated with age, anthropometric measurements and muscle strength. These findings were similar to previous studies (18) suggesting that a decrease in anthropometric measurements is associated with increased malnutrition. Patients with poor nutritional status had lower muscle strength. Recent studies regarded handgrip strength as an independent predictor and the one of the earliest markers of malnutrition (19). Although all the patients included in the study were right-handed (dominant hands were significantly stronger compared to nondominant hands) the results were still lower than those of other studies (20). Possible causes may be the financial difficulties, diets rich in carbohydrates and fat and low in vitamins and proteins and sedentarism. Studies show that malnutrition and physical inactivity may progress together and are independent predictors of mortality (21).

The geriatric evaluation revealed that malnourished patients were frailer, more

depressed and performed with difficulty or were unable to perform without assistance the IADL. These findings underline the importance of the complete assessment in older patients, as normal psychological status is essential for most activities in daily living (planning and preparing meals, food intake, and physical exercise). Other studies also observed an association between malnutrition and depression, but the relationship is complex, and it can be questioned whether depression is the cause or the consequence (22).

Malnutrition and frailty, two related syndromes, are frequently found in older patients with CKD (23). Many frailty scores include weight loss and also weight loss is considered to be a modifiable factor in frailty (24).

Regarding this objective of our study, arm and calf circumference were found to have the best power of prediction on malnutrition: AUC of 0.832, respectively 0.842, while muscle strength, depression and frailty had good accuracy also.

The consequences of poor nutritional status include low quality of life, depression, erythropoietin low-responsiveness, increased susceptibility to infections and aggravation of other chronic disorders (25). All these consequences sustain the importance of geriatric evaluation as part of managing older patients with CKD, even in the early stages of the disease.

CONCLUSIONS

Routine screening of nutritional status in older patients with CKD enables early detection and timely intervention. However, some other parameters/tests draw attention to a possible case of malnutrition (anthropometric measurements, degree of fragility, muscle strength, depression). Besides identifying patients with nutritional problems, effective strategies for the prevention and treatment of malnutrition in the increasing number of old patients at risk are needed.

THE RELEVANCE OF EUROPEAN LEUKEMIA NET RECOMMENDATIONS IN ACUTE MYELOID LEUKEMIA: A ONE CENTER THREE-YEAR EXPERIENCE (Abstract). **Aim:** The cytogenetic and molecular features of leukemia cells are chief predictors of survival in acute myeloid leukemia (AML). However, treatment outcomes in AML differ between low-, medium and high-income countries. We thus aimed to investigate the relevance of the European Leukemia Net (ELN) prognostic system in Romanian AML patients. **Material and methods:** We investigated the clinical significance of the ELN recommendations in 130 newly diagnosed AML patients treated at the Iasi Regional Oncology Institute. **Results:** Favorable, intermediate and adverse risk ELN classes had a similar distribution and retained their prognostic relevance (median overall survival of 18, 11 and 2 months respectively at a median follow-up duration of 18 months) when compared with literature data. However, in both the chemotherapy eligible and ineligible patients a higher prevalence of comorbid conditions and treatment related mortality could be identified. **Conclusions:** The management of Romanian AML patients poses significant challenges mainly due to higher incidence of comorbid conditions and infections. However, growing access to the allogeneic stem cell transplant procedure in our country will significantly improve the outcome of these patients. **Keywords:** ACUTE MYELOID LEUKEMIA, EUROPEAN LEUKEMIA NET, CYTOGENETICS, CHEMOTHERAPY.

Acute myeloid leukemia (AML) is an aggressive myeloid neoplasm characterized by extensive bone marrow (BM) infiltration with immature myeloid precursors and subsequent BM failure (1). AML diagnosis requires BM aspirate and thorough morphological, immunophenotypic, cytogenetic and molecular analysis of tumor cells (2). Furthermore, AML cases are classified in different subgroups as proposed by the 2016 revision of the World Health Organization classification of myeloid neoplasms

(3). Since AML therapy responses are highly heterogenous, ranging from deep and sustained molecular remissions in acute promyelocytic leukemia (APL) to primary refractory AML, the prognostic evaluation of patients is highly important in order to determine eligibility for more intensive therapeutic interventions, such as allogeneic stem cell transplantation (4-6). When evaluating the prognosis of AML patients, clinicians must take various factors into account, such as the antecedent hematologic disorders, radiation or cytotoxic drug exposure, hyperleukocytosis, therapy response and minimal residual disease, but also patient age, comorbidities and their performance status. However, the cytogenetic and molecular features of AML blasts are currently the strongest predictors for therapy response and long-term survival (7-10). The impact of cytogenetic and molecular anomalies is highlighted by the 2017 update of the European Leukemia Net (ELN) prognostic classification that defines three prognostic subgroups (favorable, intermediate and adverse risk) with different complete remission (CR) rates, progression and disease-free survival (11). Noteworthy, the ELN risk stratification does not take into account patient-related factors, such as age or comorbidities (12). Furthermore, recent studies revealed that prognosis in AML patients differs from high- to middle and low-income countries, probably related to inherent socio-economic issues (13, 14).

The relevance of the ELN classification in AML patients from Romania has not yet been systematically investigated. However, recently, a national program that ensures widespread access to the immunophenotyping, cytogenetic and molecular tests necessary to formulate the ELN prognostic prediction has been successfully implemented. In a recent report from the World Health Organization (15), Romanian patients have been shown to have higher incidences of cardiovascular diseases, chronic obstructive lung disease, asthma, tuberculosis and depression, all of which are known to have a negative impact on AML patient outcome (16). Furthermore, it is to be expected that the other factors reported by the WHO, such as the inequalities in patient education, the occasionally difficult access to public health services, especially in patients from rural areas, the deficiencies in the primary care system and the lowest levels of public health expenditure among the European Union member countries will likely influence the prognosis of AML in these patients (15).

The aim of our study is to evaluate the impact of the 2017 ELN classification on the prognosis of AML patients treated at the Iași Regional Oncology Institute, in North-Eastern Romania.

MATERIAL AND METHODS

A number of 130 patients diagnosed with *de novo* AML between 2017 and 2019 at the Hematology Department of the Iași Regional Oncology Institute, Romania were included in this retrospective study. AML diagnosis was established based on the 2016 WHO classification of myeloid neoplasms and patients were risk stratified according to the 2017 ELN recommendations. The cases with APL were excluded. This study was approved by the local research ethics committee. Fresh BM samples were collected at diagnosis. Immunophenotypic diagnostic of AML was established according to Euro Flow standards (17). Cytogenetic G-banding

analysis was performed using standard methods. We further examined 4 chimeric gene transcripts (BCR-ABL1 p210, PML-RARA, RUNX1-RUNX1T1, CBFB-MYH11) by reverse transcriptase-mediated quantitative PCR. Patients were tested for NPM1 and FLT3-ITD mutations. We screened for chromosome 11 rearrangements using fluorescence *in situ* hybridization techniques. In case of a dry tap, a BM biopsy and immunohistochemistry tests were performed, and cytogenetic tests were done on peripheral blood samples. Patients <65 years were treated according to the national protocol with "7+3" therapy (Cytarabine 150 mg/m^2 for 7 days in continuous i.v. administration and Idarubicine 12 mg/m^2 for 3 days). Patients > 65 years were treated with "7+3" therapy in selected cases (depending largely on the absence of comorbid conditions and an ECOG (Eastern Cooperative Oncology Group) performance status less than 2), Decitabine, low-dose cytarabine (ARA-C) or best supportive care (BSC). Post-induction response was evaluated by BM morphologic examination and flow cytometry on day 21-28 following "7+3" chemotherapy.

The statistical analysis was performed using the *IBM SPSS Statistics 21.0 Software*. The Chi square and Mann Whitney tests were used to analyze the associations between different variables. A p value <0.05 was considered to be statistically significant. Overall survival (OS) and disease-free survival (DFS) were estimated using the Kaplan Meier method. The log rank test was used for comparisons of Kaplan-Meier curves. OS was defined as the time from diagnosis to death from any cause. Early death was considered when occurring in the first 28 days following diagnosis. For the patients who achieved complete remission, DFS was defined as the time from CR to relapse or death by any cause.

RESULTS

We studied 130 patients with newly diagnosed AML. Baseline clinical and laboratory data of the patients with respect to the 2017 ELN risk classification are summarized in table I. The mean age at diagnosis was 60 years. The median follow-up duration was 18 months. 87.8% of patients presented with *de novo* AML, while 9.1% and 3.1% had secondary and, respectively, therapy-related AML. According to the WHO 2016 classification, patient distribution was the following: AML with recurrent genetic abnormalities (21.2%), therapy-related AML (3.1%), AML associated with myelodysplasia-related changes (9.1%) and AML not otherwise specified (NOS) (66.7%). 28.4% of cases presented with an ECOG (Eastern Cooperative Oncology Group) score greater than 2 due to extensive comorbidities or life-threatening complications at diagnosis.

Cytogenetic data was available in 69.2% of patients. A normal karyotype was detected in 46.7% of cases. The distribution of the cytogenetic anomalies is shown in figure 1A. 41.5% of patients had detectable molecular anomalies that are detailed in figure 1B. In 25.4% of cases we found a FLT3-ITD mutation, which co-existed with a NPM1 mutation in 21.5% of cases. An isolated NPM1 mutation was found in 30% of patients.

Following the analysis of cytogenetic and molecular data, cases were classified according to the 2 017 ELN risk classification, as follows: favorable 20.8%, intermediate 51.5%, adverse 27.7% (fig. 1C).

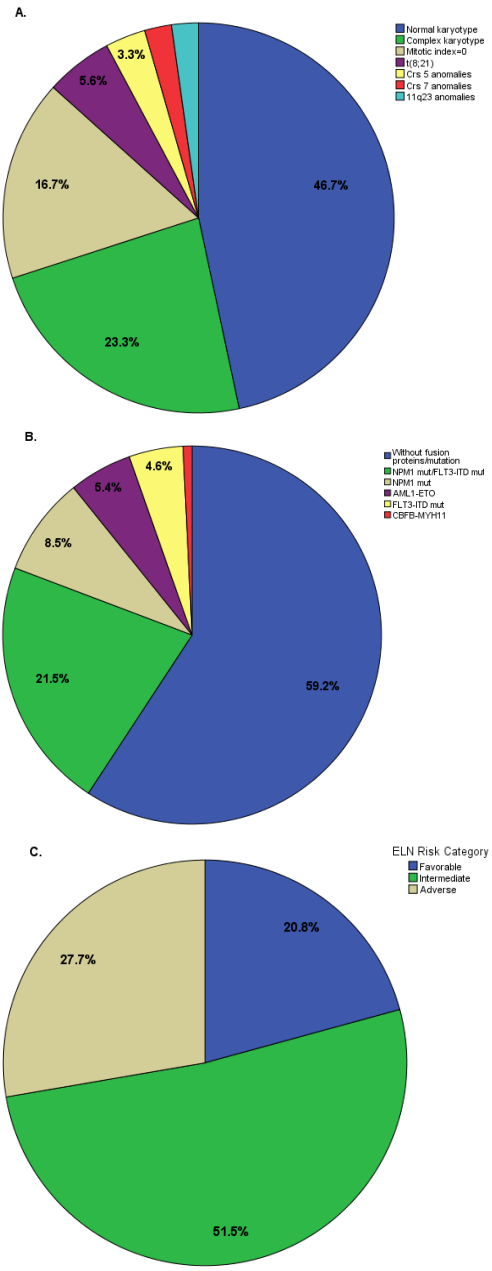

Fig. 1. A. Distribution of cytogenetic characteristics in AML patients
B. Molecular findings in AML patients
C. Distribution of ELN risk subgroups.

66.2% of patients were deemed eligible for intensive ("7+3") chemotherapy. Out of these, 81.4% completed induction chemotherapy and 58.8% achieved CR. The median OS for all patients was 12 months and the median DFS was 9 months. On ELN risk category analysis, the median OS for favorable, intermediate and adverse risk subgroups was 18 (95% CI: 12.5-23.4 months), 11 (95% CI: 7.1-14.8 months) and 2 months (95% CI: 0.8-3.1 months), respectively (fig. 2). Favorable and intermediate risk patients had DFS of 73.4% and 57.2%, respectively, while patients within the adverse category displayed the highest risk of early relapse, with a relapse rate of 75% within 3 months after achieving CR.

41.2% of chemotherapy-eligible patients had refractory disease and a median OS of 4 months. 36% of chemotherapy-eligible patients had an indication for allogeneic bone marrow transplant (ASCT). However, this procedure could be performed in only 8.1% of our patients. All patients who underwent ASCT remained disease-free at 24 months.

Out of the patients deemed ineligible for standard chemotherapy, 27.3% followed Decitabine therapy, 27.3% low dose-cytarabine (LDAC) and 45.4% received exclusively palliative care. 16.7% of the patients receiving Decitabine achieved a complete hematologic response. None of the patients treated with LDAC responded to therapy.

Furthermore, we investigated the presence of correlations between the main clinical and laboratory characteristics of patients and their ELN risk, chemotherapy completion and therapy response.

Extramedullary involvement was more frequent in the *de novo* AML-NOS subtype (p=0.008) and splenomegaly was more

frequent in patients with M7 phenotype (66.6%, p=0.009). An M5 phenotype was more frequently associated with hyperleukocytosis (33%, p=0.005) (tab. I).

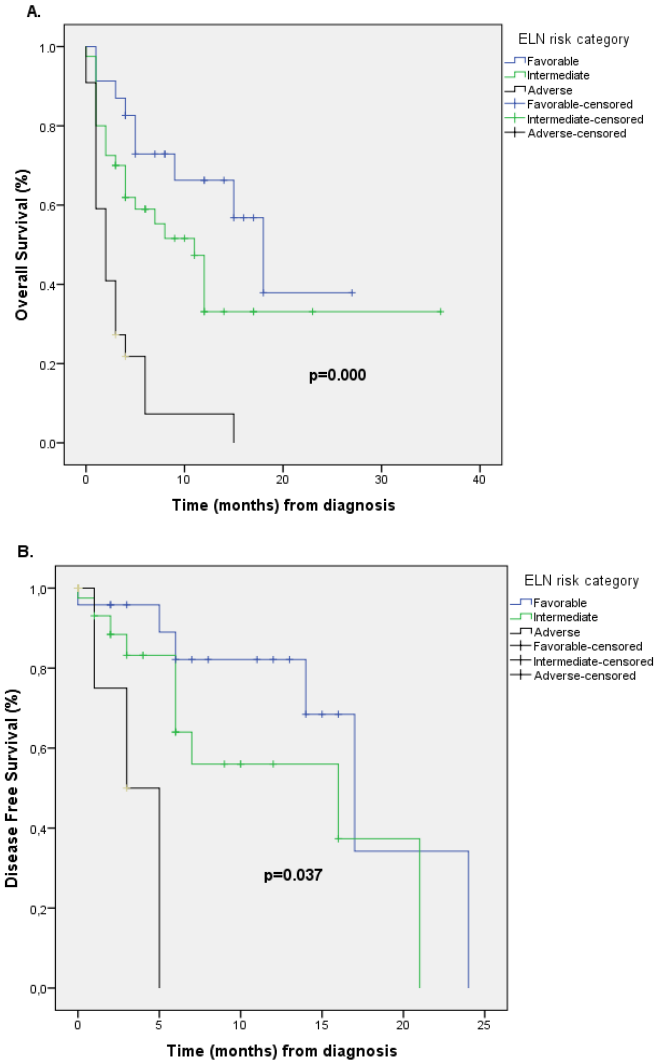

Fig. 2. Probability of overall survival (A) and disease-free survival (B) in AML patients according to the ELN prognostic system.

70.8% of patients had various associated comorbid conditions, of which the majority were represented by cardiovascular (49.2%) and metabolic (13.8%) comorbidities. 28.5% of patients had more than two associated comorbid conditions. The presence of comorbidities had a negative impact on the therapeutic response. Thus, 67.5% of patients achieving CR had comorbidities, while in patients with refractory disease their prevalence was much higher, reaching 82.9%. Moreover, the presence of infection

during or following induction chemotherapy had a detrimental effect on patient outcome. Thus, the presence of infection, irrespectively of the etiology, was associated with a 58.7% probability of refractory disease (p=0.022, Chi-Square Test). Treatment related mortality (TRM) in chemotherapy eligible patients was 16.3%. In older patients treated with Decitabine or LDAC the TRM reached 46.2%. Deaths were mainly due to infection (63.2%) or hemorrhagic complications (13.6%) (tab. I).

TABLE I

Demographic, clinical, biological, cytogenetic, molecular and therapy response data of AML patients

Patient characteristics	
Sex, n (%)	
Male	69 (53.9%)
Female	61 (46.9%)
Age

Decitabine	12 (9.2%)
Low dose cytarabine	13 (10%)
Best supportive care	3 (2.3%)
Therapeutic response, n (%)	
CR	40 (58.8%)
RD	28 (41.2%
Death in induction	14 (16.3%)

AML= acute myeloid leukemia, t-AML= therapy related acute myeloid leukemia, BM= bone marrow, CNS= central nervous system, CR= complete response, ELN= European Leukemia Net, FLT3= FMS-like tyrosine kinase, NOS= not otherwise specified, NPM1=nucleophosmin 1, RD= refractory disease, WBC= white blood count, WT= wild type

We found no further statistically significant correlation between classic risk factors such as the total white blood cell count and the WHO AML types or the response to therapy.

The log rank test was used for comparisons of Kaplan-Meier curves.

DISCUSSION

All AML patients who achieve CR are facing the likelihood of relapse (7). Thus, an accurate prognostic assessment is necessary to identify patients with high and intermediate ELN risk, who would benefit immediately from consolidation by ASCT, and patients with favorable risk, for whom high dose consolidation chemotherapy is rather indicated (11).

However, multiple reports indicated that the prognostic value of the cytogenetic and molecular features of AML can be questioned in patients from developing countries such as Romania because of local socio-economic factors (13,14). Large scale national reports regarding the outcome of Romanian patients with AML are missing and a recent WHO analysis has identified multiple issues in Romania's public healthcare system that could influence the outcome of AML patients (15). Thus, we

aimed to investigate the relevance of the ELN risk classification system in the "real-life" setting of patient1s treated at the Iași Regional Oncology Institute.

We analyzed the data of 130 newly diagnosed AML patients and we identified cases with favorable, intermediate and adverse risk with frequencies similar to those reported by other groups (18). In our study group, the ELN risk categories demonstrated survival probabilities comparable to literature data (fig. 2).

TRM in AML is defined as death within four weeks following completion of induction therapy. Literature data reveals that TRM rates vary from 10 to 30% or even more in elderly AML patients (12). Current advances in supportive care in developed countries have reduced TRM rate below 10%, even in the elderly patient population (19, 20), but death rates remain higher in developing countries. In our study group, TRM was 16.3% in chemotherapy eligible patients. However, in elderly patients treated with Decitabine or LDAC, mortality was much higher, reaching 46.2% (data not shown). The high TRM rates in our study group are mainly due to infectious and hemorrhagic complications, but also to associated comorbid conditions. Poor education, inadequate hygiene habits, especially in patients from rural areas, irrational antibiotic use in the general population and colonization with multidrug resistant bacteria all contribute to a higher incidence of infection among our patients when compared to reports from more developed countries (18). Comorbidities, especially cardiovascular ones, which have a higher prevalence among Romanian patients (15), further contribute to even a higher mortality among patients with infectious complications. Moreover, the presence of infection at diagnosis delays the administration of induction therapy and the development of severe, life-threatening sepsis during induction chemotherapy forfeits its completion, which compromises therapeutic response and leads to a dismal prognosis. Thus, the median survival in patients who did not complete induction therapy was 5 months (data not shown). Moreover, the higher incidence of infection also reduces survival in the group of AML patients with favorable ELN risk.

Although the majority of patients were classified as intermediate or adverse risk, allogeneic stem cell transplant was performed only 8.1% of patients. Timely access to this procedure is vital for the survival of AML patients (21). Widespread availability of this procedure remains a major unmet need for Romanian AML patients, even if, in the last years, Romania is cited by reports from the European Bone Marrow Transplantation Society as one of the European countries with a rapid increase in transplanted cases per year (22, 23). Thus, it is expected that the access to this procedure will improve drastically in the near future.

We can conclude that the ELN risk assessment system is relevant for Romanian AML patients, but infections, more frequent comorbidities and the lack of timely access to the bone marrow transplant procedure have a detrimental influence on their short- and long-term prognosis.

CONCLUSION

In our study we examined the relevance of the European Leukemia Net prognostic system in AML patients treated at the Regional Institute of Oncology from North-Eastern Romania. Briefly, we conclude that the ELN risk classes have similar distribution when compared to literature data. Fur-

thermore, despite a higher incidence of comorbidities among Romanian patients and higher treatment related mortality rates in both the chemotherapy eligible and ineligible patients, the ELN prognostic system retains its significance. However, more prevalent comorbid conditions, poor hygiene habits, treatment discontinuation and low availability of the bone marrow transplant procedure can pose major challenges in the management of AML and impact the long-term prognosis of patients.

NEWS

THE INTERPLAY BETWEEN VAGINAL MICROBIOTA AND INTRAUTERINE ADHESION USING NEXT GENERATION SEQUENCING METHODS

Intrauterine adhesion represent a disease that is a very common cause for female infertility. Since it has an increased recurrence rate after surgical interventions, its pathogenesis and recurrence causes are important to understand better this condition. Liu *et al*. (2019) analysed, using high-throughput sequencing method, the vaginal microbiota of females diagnosed with intrauterine adhesion and healthy patients` vaginal secretion. The results shown that intrauterine adhesion does not bring any important changes for vaginal microbiota, having a slighty effect on the number of vaginal bacterial species. The patients with intrauterine adhesion presented at the phylum level a reduced percentage of Firmicutes and increased percentage of Actinobacteria whereas in the healthy females group the rate was more lower ($P<0.05$). Moreover, in about half of the intrauterine adhesion vaginal samples was identified at the genus level a remarkable decreased number of Lactobacillus and enhanced growth of Prevotella and Gardnerella ($P<0.05$). The interplay between synechiae and vaginal microflora can reveal remarkable changes in the vaginal microbiota diversity in patients with intrauterine adhesion. The increase of Lactobacillus population may bring interesting benefits in the endometrial regeneration process but also may help to decrease de recurrence rate of intrauterine adhesion (Liu Z, Kong Y, Gao Y *et al*. Revealing the intraction between intrauterine adhesion and vaginal microbiota using high-throughput sequencing. *Mol Med Rep*. 2019. 19(5),4167-4174).

EVALUATING PREDICTIVE FACTORS FOR DISEASE ACTIVITY AMONG PATIENTS WITH INFLAMMATORY BOWEL DISEASE

EVALUATING PREDICTIVE FACTORS FOR DISEASE ACTIVITY AMONG PATIENTS WITH INFLAMMATORY BOWEL DISEASE (Abstract) **Aim**: this study focused on evaluating several potential predictive factors for an increase in disease activity at 6 months for patients with inflammatory bowel disease (IBD). **Material and methods**: We performed a prospective cohort study, including patients who were evaluated at baseline and at 6 months. We assessed disease activity, clinical and biochemical parameters, anxiety and depression using Hospital Anxiety and Depression Scale (HADS) and sleep disorders using Pittsburgh Sleep Quality Index (PSQI) both at baseline and at 6 months. **Results:** Among the 59 patients who completed the follow-up, there was a statistically significant correlation between the presence of hyposideremia (p=0.023), hypercholesterolemia (p= 0.015) and altered psychological state (p=0.006) at baseline with an increase in disease activity at 6 months. Moreover, among the studied parameters, hypercholesterolemia (OR 5.18; 95% CI, 1.25-21.44), the neutrophil to lymphocyte ratio (OR 3.83; 95% CI, 1.87-7.83) and the depression score (OR 1.56; 95% CI, 1.22-2.01) were predictors for increase in disease activity at 6 months. **Conclusions:** Beyond usual inflammatory markers, neutrophil to lymphocyte ratio could have potential predictive value for systemic inflammation in IBD patients and could be easily assessed at routine evaluations. An integrative management, addressing several comorbidities, such as dyslipidemia and alteration of psychological distress could contribute to diminishing the risk for future disease flares in this patient category. **Keywords**: INFLAMMATORY BOWEL DISEASE, PREDICTIVE FACTORS, HADS.

Inflammatory bowel disease (IBD) represent chronic inflammatory disorders which evolve with a relapsing-remitting pattern and include two main subtypes, namely ulcerative colitis (UC) and Crohn's disease (CD). Although with increasing prevalence in the past decades, there is still no curative treatment and relatively few information on the factors which could predict disease evolution. After diagnosis, disease monitoring is essential via clinical, biological and endoscopic criteria but also through evaluation of disease activity scores, the most commonly used being Mayo score for UC and Crohn's disease activity index (CDAI) for CD.

Although non-invasive disease monitoring following various biological parameters

reflecting inflammation such as C reactive protein (CRP), fibrinogen, fecal calprotectin is available (1) less information is available on noninvasive parameters predictive for future disease activity. Identifying predictors of unfavorable clinical course are useful, since they could facilitate treatment decisions, indicate requirement for tight monitoring and avoid overtreatment (2). Our aim was to identify potential predictive factors for increased disease activity at 6 months evaluation among several accessible parameters in the clinical practice.

MATERIAL AND METHODS

This prospective study assessed the prediction value of several parameters for disease activity at 6 months and included IBD patients from the Institute of Gastroenterology and Hepatology from "Sf. Spiridon" County Clinical Emergency Hospital, Iași, Romania between September 2019 and February 2020, who were evaluated at baseline and at 6 months.

Inclusion criteria were age above 18, written informed consent, diagnosis of IBD based on clinical, endoscopic and histological criteria. The exclusion criteria included refusal to participate in the study, active infections and various aspects which might influence psychological status and sleep quality (9): pregnancy, history of neoplasia, previously diagnosed psychiatric disorders, history of alcohol or drug use, sleep apnea, BMI > 35, significant major associated illness (active malignancy, significant cardiac or pneumological comorbidities), night shift workers, and associated medications (analgesics, muscle relaxants, antineoplastic agents, thyroid medication).

For the enrolled patients, clinical and anamnestic data were collected during patients' evaluations, including information related to extraintestinal manifestations, current and previous medication, IBD- related surgery. For the evaluation of disease activity, Crohn's Disease Activity Index (CDAI) was used for patients with CD and Mayo score for UC. The biochemical evaluation included not only markers of systemic inflammation, namely C reactive protein (CRP), erythrocyte sedimentation rate (ESR) and fibrinogen, but also evaluation of the complete blood count (CBC) with calculation of neutrophil-/to-lymphocyte ratio (NLR), iron level, ferritin, albumin, cholesterol, triglycerides. Sleep quality was assessed using the Pittsburgh Sleep Quality Index (PSQI) and psychological distress was evaluated through the Hospital Anxiety and Depression Scale (HADS). Impaired sleep was defined as a PSQI ≥5 (3), while altered psychological status was considered when either of the 2 HADS sub scores, namely HADS-depression (HADS-D) and HADS-Anxiety (HADS-A) were ≥8 (4). All these parameters have been evaluated at baseline, while at 6 months clinical and anamnestic data, CBC, inflammatory markers (CRP, fibrinogen) were recorded and disease activity scores (CDAI, MAYO) calculated.

The data was statistically analyzed using *SPSS version 25*. Variables were reported as mean values and standard deviation, or as median with 25th-75th percentiles, after testing for normality of the distribution using Kolmogorov-Smirnov test. To evaluate the homogeneity of variance, Levene test was used. The comparisons between the analyzed groups were performed using Student's t-test for normally distributed continuous variables.

The qualitative variables were presented as absolute (n) and relative (%) frequencies and the comparison among the groups was based on the results of Chi-square tests. The

bivariate correlation analysis was completed based on Pearson Correlation test. Predictive value for several parameters was evaluated using logistic regression and variables with significant results were afterwards included in the multivariate analysis. ROC curve analysis was used to evaluate the prediction power of some variables. For all tests applied, the calculated significance level (p-value) was considered for $p < 0.05$.

The study protocol was in accordance with the ethical standards of the institutions' Ethical Review Boards and with the 1964 Helsinki declaration and its later amendments and the study was performed after obtaining approval from the institutions involved.

RESULTS

Among the 82 eligible patients with IBD, 59 completed the study; 6 did not consent for participation in the study, 14 could not complete the follow-up, 2 had active infection, 1 had history of neoplasia. For the 59 patients included in the study several characteristics were evaluated, with no statistically significant differences between these parameters depending the disease subtypes (Crohn's disease and ulcerative colitis) (tab. I).

TABLE I

Descriptive statistics of the evaluated parameters

Patient characteristics	Study Group n=59 (100%)			Statistic test	*p-value* (*)
	Ulcerative colitis n=41 (69.5%)	Crohn's Disease n=18 (30.5%)

In order to identify potential predictive value for increased disease activity at 6 months, reflected by increased values of CRP and fibrinogen, we evaluated potential correlations with parameters such as anemia (defined as Hb<12 g/dL for female patients and <13 g/dL for male patients), hyposideremia (seric iron level <50 mg/dL), hypercholesterolemia (Cholesterol level>200 mg/dL), extraintestinal manifestations, impaired sleep (PSQI ≥ 5), altered psychological status (HADS-A and/or HADS-D ≥ 8). Pearson test revealed a statistically significant correlation between the presence of hypercholesterolemia (p=0.015) and altered psychological status (p=0.06) at baseline with increased values of CRP at 6 month evaluation; moreover, hyposideremia (p=0.023), hypercholesterolemia (p=0.01) and impaired sleep (p=0.039) at baseline were correlated with increased fibrinogen value at 6 month evaluation IBD patients (tab. II).

TABLE II

Correlations between various parameters at baseline and increased inflammatory markers (CRP, fibrinogen) at 6 months

Parameters evaluated at baseline	Increased CRP value at 6-month evaluation IBD patients (p value)	Increased fibrinogen value at 6-month evaluation IBD patients (p value)
Anemia	0.118	0.852
Hyposideremia	0.054	0.023*
Hypercholesterolemia	0.015*	0.01*
Extraintestinal Manifestations	0.198	0.274
Impaired sleep	0.960	0.039*
Altered psychological status	0.006*	0.256

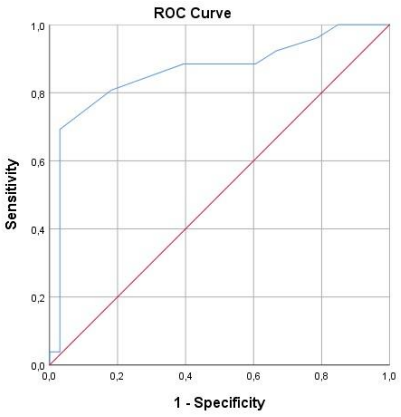
Pearson correlations, (*) marked effects are significant for $p < 0.05$

Considering the previously mentioned findings, logistic regression was used to identify predictors of sleep quality and examine the effect of various parameters at baseline for increase in disease activity at 6 months. In the study group, the univariate analysis showed that the presence of hyposideremia (OR: 13.09; 95% CI: 1.57-109.11), hypercholesterolemia (OR: 5.18; 95% CI: 1.25-21.44), the values for NLR (OR 3.835; 95% CI, 1.87-7.83) and HADS-D (OR 1.56; 95% CI, 1.22-2.01) at baseline were predictors for an increase of disease activity at 6 months. In the multivariate analysis, however only hyposideremia was identified as a predictive factor (tab. III).

TABLE III
Evaluation of the prediction power of various parameters on increase in disease activity at 6 months

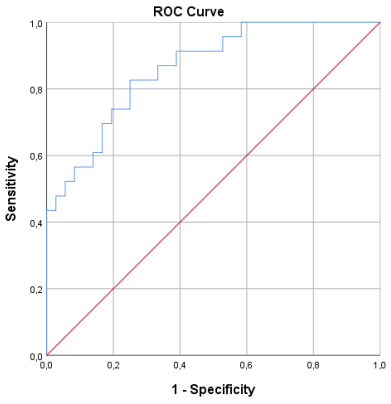
Parameter	Univariate analysis Study Group OR 95% CI	Multivariate analysis Study Group OR 95% CI
Anemia	1.77 (0.42-7.39)	
Hyposideremia	**13.09 (1.57-109.11)**	**9.63 (1.05-87.75)**
Hypercholesterolemia	**5.18 (1.25-21.44)**	3.38 (0.71-15.95)
Extraintestinal manifestations	3.77 (0.44-32.36)	
Impaired sleep	2.47 (0.59-10.31)	
NLR	**3.83 (1.87-7.83)**	0.54 (0.25-1.15)
CRP / ALB	0.31 (0.04-2.08)	
HADS-D	**1.56 (1.22-2.01)**	0.99 (0.79-1.25)
HADS-A	0.96 (0.79-1.15)	
PSQI	1 (0.85-1.18)	

Increased disease activity was defined as an increase in MAYO and respectively CDAI score at 6 months compared to baseline since NLR and HADS-D might have predictive value on the increase of the inflammatory parameters, we used ROC curve analysis in order identify a cut-off value for these parameters, which could predict active disease at 6 months. Consequently, we identified a cut-off value of 2.7 for NLR and a cut-off value of 8.5 for HADS-D at baseline to be predictive for an increase in disease activity at 6 months (fig. 1).



(a)

Cut off value	2.7
AUC	0.862
Sensibility	0.826
Specificity	0.722
p value	0.001



(b)

Cut off value	8.5
AUC	0.853
Sensibility	0.808
Specificity	0.82
p value	0.001

DISCUSSION

Considering that IBD represent diseases with a relapsing-remitting pattern, with high disease burden, but also with significant socio-economic impact (5), there are efforts in identifying potential predictors of disease severity and disease flares. In the current study, we searched for parameters which could be easily used in the clinical practice to predict future disease flare and consequently to identify patients who require tight monitoring, for better disease control.

We have identified several factors that could contribute to predicting disease activity at 6 months in IBD patients, among parameters that are or could be routinely evaluated. Among the biochemical parameters we identified increased NLR, low seric iron level and hypercholesterolemia as predictors for active disease at 6 months. An interesting finding was that the presence of hyposideremia, but not necessarily the presence of anemia constituted predictive factors for disease activity, which highlights once more the importance of diagnosing and correcting the low iron levels in patients with IBD, as this influences disease-related outcome (6). This could be due to the coexistence of inflammation (either clinical or subclinical) with histologic changes, which play a role in iron deficiency, probably mediated by the hepcidin-ferroportin axis (7).

As far as the other biochemical markers are concerned, NLR has been investigated as marker of subclinical inflammation and it can be easily available from the CBC. A study performed by Acaturk G *et al.*, investigated the utility of NLR in evaluating disease activity in IBD patients and identified an NLR cut-off point for active CD and UC was 3.2 and 3.1. In our study, a cut-off NLR of 2.7 was a predictor for disease activity at 6 months (8).

Regarding other parameters identified as potential predictors for active disease at 6 months, we identified that psychological distress correlated with the presence of inflammatory syndrome at 6 months. Our findings also included that increased depression, but not anxiety score is predictive for active disease at 6 months. Psychological comorbidity is important in the evolution of IBD, as it can promote inflammation and it can be associated with sleep impairment which could enhance the effects of psychological distress on the proinflammatory status (9). Moreover, there is a potential bidirectional relationship between psychological status and IBD activity, with inflammation driving depression and vice versa (10). Considering that several studies have highlighted that the presence of depression and anxiety generates a subsequent worse course of disease compared to IBD patients without psychiatric comorbidity (11-14), early identifying and targeting the associated psychological impairment could contribute to improving disease control (10). Considering that, we evaluated a potential cut-off value for HADS-D of 8.5 as predictive for disease activity at 6 months. This aspects could support the role of screening for depression among IBD patients, so that the psychological comorbidity could be addressed and consequently to improve disease outcome.

Although the univariate analysis highlighted significance for all the abovementioned parameters, when using multivariate analysis to study the parameters, we did not obtain significant results; however, this is most probably due to low sample size and is the main limitation of our study. Therefore, prospective cohort studies with large number of patients should be per-

formed in order to further evaluate easily available markers with predictive value for disease activity and lead to improving IBD patients' management.

CONCLUSIONS

There is an increased need for identifying predictive factors for disease activity in IBD patients in order to optimally tailor the disease monitoring and adjust treatment. Among commonly assessed parameters, hyposideremia, hypercholesterolemia, increased NLR and the presence of depression symptoms show promising value as predictive factors and could be easily followed in the daily clinical practice.

URINALYSIS UNDER THE MICROSCOPE: FAST, CHEAP AND COMMON BUT STILL RELEVANT (Abstract) **Aim:** The complete urine examination consisting of the analysis on the strip and the manual microscopic examination is one of the most important and used tests in current medical practice. The purpose of this study was to compare the efficiency of the strip vs the microscopy, but also the results obtained from the hospital compared to those from the ambulatory. **Material and methods:** The present study is a retrospective study conducted on a batch of 103 patients (53 hospitalized, 50 outpatient) between July and August 2019, with samples processed in the Clinical Laboratory of Medical Analyses of the Clinical Emergency Hospital for Children "Louis Țurcanu" Timișoara. Of the 103 patients, 63 (61.2%) were female, while 40 (38.8%) were male. **Results:** The red blood cells (RBCs) reading with the help of the strips and the bio-analyzer revealed negative results in 85.4% of the samples, while the microscopic examination revealed only 59.2% negative results. The same trend could also be observed in the case of leukocytes: 81.6% negative results on the strip, 20.4% results negative on microscopic examination. The *p* values for both examinations were <0.0001. Comparing hospital patients and outpatients, 5 entities (epithelia, bacteria, leukocytes, RBCs, and salts) were chosen, which were then divided by frequency (absent, very rare, rare, relatively common, common, numerous and deposit). Percentage values between the two groups were similar. *ANOVA* tests revealed the no difference either, *p* values being over 0.9277 when considering the absent values and over 0.1956 when excluding absent values. **Conclusions:** The difference between strip and microscope analyses for RBCs and leukocytes has proved to be statistically significant. No major percentage differences were identified between hospital and ambulatory for the number of positive samples for the epithelial variables, salts, leukocytes, RBCs, or bacteria. **Keywords:** URINALSYS, URINARY STRIPS, MICROSCOPY.

The urinalysis is one of the most important habitual tests that can be performed in a medical analysis laboratory and is used for prevention, screening, monitoring and diagnosis. It is widely used for early diagnosis but also for empirical treatment of urinary tract infections (UTI) (1).

There are two parts that can be distin-

guished in performing an urinalysis. These are the automatic reading with an analyzer of urinary dipsticks and the microscopy of the centrifuged urine. The advantages of using the urinary strips are the low cost, the ease of interpretation as well as the short effectuation time. In addition, this procedure can be performed by minimum qualified personnel using an analyzer, while the view under the microscope is performed by higher trained personnel (2).

The efficiency of strips has been proven amongst pediatric population, including under the 2 years old as a screening method of UTI as well as other pathologies (3). The examined parameters are as follow: pH, concentration, leukocyte esterase, presence of red blood cells, nitrite levels, urobilinogen, ascorbic acid, glucose levels, ketone bodies, bilirubin, or proteins (especially albumin) (4).

The microscopy of centrifuged urine has the advantage that it can give both a quantitative but also qualitative result for the number of leukocytes and red blood cells, but it is also useful for the objectification of bacteria, salts, and epithelia (5, 6).

The urinalysis represents a useful test in diagnosing of different renal-urinary pathologies. Although the microscopic examination contains a subjective characteristic represented by the examiner (based on training, experience), the fact that the test executes a qualitative analysis (7, 8), not only quantitative of the elements that can be found in the urine sample, makes it have a higher value of examination than in the case of strips reading (9, 10). Given this hypothesis, we study if the microscope examination leads to more accurate results than strips analysis.

MATERIAL AND METHODS

This study is retrospective, observational and includes the pediatric patients hospitalized in Emergency Hospital for Children "Louis Țurcanu" Timișoara and the outpatients, who underwent a complete urine examination (strips and microscope) between July-August 2019. After the identification of relevant patients, demographic (sex, age) and paraclinical (quantitative and qualitative data from previously performed tests) data were collected from the electronic archive of the hospital. Besides the above criteria, the main inclusion criterion was represented by the age below 16 years.

The examined group includes 103 patients distributed relatively equal in two subgroups: hospitalized patients and outpatients. Whereas it is reasonable to expect that the hospitalized patients to be suffering from more serious pathologies than the outpatients, we can assume the hypothesis that their urinalysis results would agree with the severity of their pathologies (11-14).

The results that are the subject of this study were obtained using strips with parameters, urine bioanalyzer *LabURreader Plus* for reading the strips and for microscopy it has been used a Nikon microscope. The microscope glass slides were viewed with a 40x magnification objective. All the samples were processed in the laboratory of medical analysis of the Emergency Hospital for Children "Louis Țurcanu" from Timisoara, which is accredited by RENAR.

Statistical analysis

The data obtained were processed statistically using *Microsoft Excel version 14.0* and IBM *SPSS Statistics 25.0*. We have also calculated a 95% confidence interval (C.I. 95%) for means by using the Wilson method. Due to having a small sample, *Fisher's* test with two tails was performed for comparison between strips and microscopy finding. For analysis between hospital patients and outpatients, an *ANOVA* test

was performed for each entity (epithelia, bacteria, leukocytes, RBCs, salts)

RESULTS

During the given period, there were identified 103 patients, which met the criteria for inclusion in the study. Of them, 63 (61.2%) were females and 40 males (38.8%). The median age of the group was 8 years old, with a minimum age of one month and a maximum age of 16 years old (tab. I).

TABLE I
Distribution of the pediatric population

Sex	No.	Percentage	C.I. 95%
Female	63	61.2%	51.52 - 70.02
Male	40	38.8%	29.98 - 48.48

Microscopy *vs.* Strips

Following the descriptive analysis of the database, we obtained the second table, which shows a remarkable difference between the results of the centrifuged samples seen under the microscope and those of the strips, read in the analyzer. The presence or absence of red blood cells and leukocytes were described in the table because they are common elements between the two parts of the complete urine examination.

For the positive results, we do not consider that the detail regarding the number of leukocytes or red blood cells is relevant because the microscopic reading measures the number of elements present in the field while the strip performs a semi-quantitative analysis and has as a unit of measure mg/dL (tab. II). *Fisher's test* returned p value of < 0.0001 for both RBCs and leukocytes, resulting in a statistically significant difference between the two methods.

TABLE II
Difference between the results of the strips read in the analyzer and those of the centrifuged samples seen under the microscope

	Strip reading with analyzer						Urinary sediment by microscopy						p
	Negative		C.I. 95%	Positive		C.I. 95%	Negative		C.I. 95%	Positive		C.I. 95%	
RBCs	**88**	85.4%	77.36-90.97	**15**	14.6%	9.03-22.64	**61**	59.20%	49.56-68.21	**42**	40.8%	31.79-50.44	< 0.0001
Leukocytes	**84**	81.6%	72.97-87.86	**19**	18.4%	12.14-27.03	**21**	20.4%	13.74-29.17	**82**	79.6%	70.83-86.26	< 0.0001

Hospital *vs.* Ambulatory

We identified two sublots consisting of outpatients (n = 50) and patients hospitalized (n = 53). Starting from the hypothesis that the hospitalized patients should have worse results than in the ambulatory, we wanted to see if there are differences between the percentages of negative and posi-

tive samples for the variables of leukocytes, red blood cells, epithelia (both flat and round), salts (whether we are talking about amorphous salts, Ca oxalates, amorphous urates, ammonia-magnesium phosphates) and bacteria within the two groups.

The number of negative samples for epithelia, blood vessels and salts had similar percentage values between hospital and outpatient groups. The same is true for leukocytes with a major difference between the two percentages. The only variable that is more common in the hospital than in the outpatient setting is the presence of bacteria. Thus, no significant differences were found between the two sublots, but the small differences of several percentage points tilt the balance in favor of outpatients regarding the number of positive samples on the studied variables (tab. III).

TABLE III

The number and the percentages of negative and positive samples for the variables investigated within the two groups

p1: result of ANOVA test taking “absent” values into consideration;
p2: result of ANOVA test excluding “absent” values;

Two *ANOVA* tests were done. The first considered the "absent" values and the p values are recorded into column p1 from third table. The second excluded the "absent" values and the p values are recorded into column p2 from third table. Both p1 and p2 values are more than 0.05, revealing the fact that there are no statistically significant differences.

DISCUSSION

Countless studies have shown an increased incidence of UTI in the female population compared to the male population (15). The predominance of the female sex in the studied group is not random because it is known that women have more UTIs than men due to the anatomical differences of the genitourinary system. However, in the first months of life there were no significant differences regarding this incidence.

Although the reading of the urinary sediment from the centrifuged urine obtained positive results regarding the variables of the red blood cells and leukocytes in higher percentages than the reading of the strips by the urine bio-analyzer, we must also discuss the differences between the two test methods. On the one hand, the reading on the strip is done by interpreting the color change reaction that the reagent on the strip paper has at the time of contact with the sample, thus obtaining a semi-quantitative reading expressed in mg/dL. In addition, it should be mentioned that the strip reacts to leukocyte esterase and then estimates the number of leukocytes (16). On the other hand, the results given by microscopy are subjective, depending on the examiner's skill (17) and for the number of elements present in the field, a standardization table of the number of elements is used as follows: very rare (0-2 elements per field), rare (2-5 items per field), relatively common (5-10 items per field), common (10-40 items per field), numerous (26-40 items per field) and deposit (more than 40 items per field) (18).

Our hypothesis that it is reasonable to expect that the results of patients admitted to the hospital to be more frequently modified than normal than those presented in the outpatient setting cannot be supported by the results obtained on our batch of patients. The complete urine examination is a routine test and most likely, the large number of pathologies for which pediatric patients in our hospital are admitted far exceeds the reno-urinary sphere for which this examination is mostly relevant. Thus, one can explain the large number of samples from the hospital that did not necessarily have elements of pathogenicity (19). At the same time, patients sent to the outpatient laboratory by the primary care services (family medicine, outpatient offices of specialist doctors) with a referral ticket are often targeted for the pathologies of the genitourinary sphere with changes in the urinary sediment, being thus used to diagnose or at least to make a correct differential diagnosis (20).

CONCLUSIONS

Our results showed that microscopic examination revealed more positive results than the test on the strip and that the difference was statistically significant. The hypothesis according to which the admitted cases show more frequent and more serious changes than those in the outpatient turned out to be false, since the results obtained by us showed similarities between the two sublots.

PARTICULAR ASPECTS IN PATIENTS WITH PARANEOPLASTIC DEEP VEIN THROMBOSIS: FROM A SHADOWY DIAGNOSIS TO A ROUTINELY MET PATHOLOGY (Abstract). The oncological patient presents many pathophysiological particularities, including a hypercoagulable state, which causes frequent thromboembolic complications. Furthermore, the side effects of chemotherapy, laborious surgical interventions and the poor performance status favor the occurrence of deep vein thrombosis (DVT). The aim of this retrospective study is to identify the prevalence of paraneoplastic DVT in patients admitted in the Cardiology Department of the "Sf. Spiridon" County Clinical Emergency Hospital from Iași and to establish the correlations between the DVT, type of neoplasia and certain particularities of the patients. **Material and methods**: The current retrospective study was conducted over a two-year period and enrolled 100 patients divided into two groups based on the presence or absence of a neoplasia (25 patients having a tumoral pathology and 75 patients without such a comorbidity). All study participants underwent a complete clinical examination and were assessed through biochemical and echocardiographic parameters. **Results:** Various tumor locations were identified in the 25 patients with a malignancy, the most prevalent being the colorectal cancer (6 cases, 24% of total), followed by the lung cancer (4 cases, 16%) and, with a similar occurrence, the brain, ovarian and breast cancer (2 cases each, 8%). Among the patients with neoplasia, 13 had a history of cancer (52% of cases from the neoplasia group), while for the remaining 12 patients it was a *de novo* diagnosis. **Conclusions**: Patients with DVT showed a significant cancer prevalence, either previously diagnosed or incidentally discovered. The increased risk of DVT in cancer patients is multifactorial and represents a diagnosis and therapeutic challenge. In our study, we recorded a slightly increased prevalence of cancer in women (56% vs. 44%), who had cervical cancer as the most common etiology (35.7%). On the other hand, male sex was associated with an increased frequency of colorectal cancer (36.4% of all cancers diagnosed in men), followed by lung cancer (27.3%). **Keywords:** DEEP VEIN THROMBOSIS, CANCER, PARANEOPLASTIC SYNDROME.

Deep vein thrombosis (DVT) is an underdiagnosed and serious, yet preventable medical condition that can cause disability and death. DVT is the formation of a blood clot usually in the lower leg, thigh, or pelvis venous networks, but they can also

occur in the arm (1, 2).

The incidence of DVT increases sharply with age and appears steady over the last years, despite extensive preventive strategies. Women are more often affected at younger ages, but this ratio is reversed in the case of elderly patients. It is predicted that the number of DVT will continue to increase, and by the year 2050, the prevalence is expected to reach approximately 1.8 million cases per year in the United States (3). Recent European population studies reported a DVT incidence of 70-140 cases/100,000 person/year (4).

Cancer and thrombosis are connected through a well-established interdependence. DVT contributes significantly to the morbidity and mortality of cancer patients, with a fatal pulmonary embolism (PE) being three times more common in cancer patients compared to non-cancer patients. In a similar way, approximately 15% to 20% of patients with malignancy will develop venous thrombosis, whereas 18% to 20% of idiopathic venous events are caused by an occult neoplasia, (5). Annually, 0.5% of cancer patients will experience a thrombotic event, compared to a 0.1% incidence rate in the general population, furtherly confirming the mutual relationship between these two pathologies (6).

Studies have shown that many patients who had developed DVT were diagnosed with a type of neoplasia in the 12 months following the thromboembolic event. It is also estimated that cancer patients who develop DVT have a 94% probability of a fatal event in the 6 months following the episode. Therefore, DVT can be considered a negative predictive marker of survival in cancer patients (7).

The evolution of both DTV and a neoplasm can be unpredictable, a sufficient reason for an adequate approach of these fragile patients, with a careful assessment of the risks and benefits of each intervention, in order to prevent major complications.

The aim of this retrospective study is to identify the prevalence of DVT in patients admitted in the Cardiology Clinic of the "Sf. Spiridon" County Clinical Emergency Hospital from Iasi and to establish the correlations between the type of neoplasia and the patients' characteristics. Therefore, we assessed the prevalence of DVT and analyzed the included patients according to gender, age, tumor location, type of onset and we also identified some particularities concerning the paraclinical profile or other investigations used to detect the neoplastic etiology of DVT.

MATERIAL AND METHODS

The current study was conducted over a two-year period (2018-2020) and included 100 consecutively enrolled patients, admitted in the Cardiology Clinic of the "St. Spiridon" Emergency Clinical Hospital with DVT. The patients were divided into two categories, based on the presence of a neoplasia (25 patients with a neoplasia and 75 patients without a neoplasia).

For all of the patients, a detailed medical history, physical examination, blood pressure measurement, electrocardiogram recording, and echocardiography evaluation were performed. The diagnosis of DVT was established based on the clinical manifestation, biochemical parameters, and ultrasound imaging. A complete blood count was the initial step of the laboratory diagnosis, followed by D-dimers determination (a value over 5 microgram/ml was considered significant). Venous Doppler ultrasound of the affected lower limb re-

vealed the presence and location of the thrombus. Moreover, various paraclinical investigations aiming to identify the etiological tumor were performed: chest X-ray, abdominal ultrasound, uro-genital examination, PSA, and abdominal and pelvic computed-tomography.

Additionally, the patients were examined for potential complications or comorbidities which may interfere with an appropriate therapeutic management. By far, the most severe complication of DVT is represented by the pulmonary embolism (PE); consecutively, an electrocardiogram, an echocardiography, a chest X-ray, and a computed pulmonary angiography were performed. In order to identify the comorbidities, the anamnesis and personal files represented important aspects, as well as the usual paraclinical investigations (regarding the renal function, glycemia, lipid profile and urinalysis).

We excluded the patients with venous thrombosis located in the upper limbs, lower vena cava or mesenteric veins and the patients who refused to have a complete cardiological evaluation or who did not agree with some exploratory investigations.

Statistical analysis was carried out using the *SPSS 20.0* software and *Microsoft Excel 2010*. Data were expressed as mean ± standard deviation or number of cases with percentage, for continuous and ordinal variables. For all data, a two-sided p value < 0.05 was considered statistically significant.

RESULTS

For the age-based comparative analysis we divided our patients into three groups: aged < 50 years (19%), aged 50-70 years (51%) and aged > 70 years (30%). Their mean age was 60.52 years. Of the entire cohort, 52% were males. The statistical analysis included several parameters, either derived from the characteristics of DVT (location, mode of onset, first episode or reoccurrence) or a selection of some usual laboratory markers.

Concerning DVT location, 56% of the patients presented a thrombosis of the right lower limb, while 52% of the entire cohort suffered from PE, which is the main complication of DVT.

Anemia represents a negative prognosis factor in cancer patients; therefore the immediate assessment of serum hemoglobin is a step of utmost importance. The presence of anemia in 38% of the included patients (expressed as a Hb<12 g/dL for women and <13 g/dl for men) required additional investigations in order to highlight the DVT etiology and, eventually, the tumor existence. In our study, we observed no significant gender-based differences concerning the presence of anemia, PE or cancer (tab. I). Very interestingly, statistical analysis revealed a significant correlation between a Hb>14 g/dL and the diagnosis of PE (p = 0.05).

Various tumor locations were identified in the 25 patients with malignancy, colorectal cancer having the highest percentage (6 cases, 24%). In the second place came the cervical cancer, diagnosed in 5 patients (20%), followed by the lung cancer (4 cases, 16%) and, in equal percentage, by the brain, ovarian and breast cancer (2 cases each, 8%). A detailed report can be found in first figure.

Among female patients, cervical cancer was the most commonly documented neoplasia (35.7%), a situation distinct from male patients, who were predominantly suffering from colorectal neoplasm (4 cases, 36.4%). More information can be found in first table.

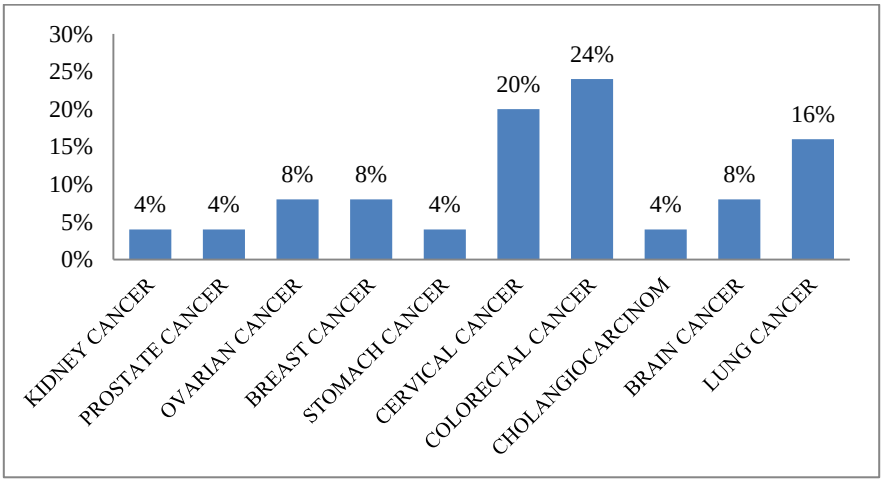

Fig. 1. The prevalence of different type of neoplasia in the study group

TABLE I

Gender-based differences between the presence of anemia, PE or cancer

Pathology	Men	Women	*p*
Pulmonary embolism	30 (57.7%)	22 (45.8%)	0.235
Anemia	23 (44.2%)	15 (31.3%)	0.181
Cancer	11 (21.2%)	14 (29.1%)	0.355

TABLE II

Cancer type distribution according to gender

Gender	Type of cancer	Number of cases	Percentage (%)
Female	Lung cancer	1	7.1 %
	Brain cancer	1	7.1 %
	Cervical cancer	5	35.7 %
	Colorectal cancer	2	14.3 %
	Stomach cancer	1	7.1 %
	Breast cancer	2	14.3 %
	Ovarian cancer	2	14.3 %
Male	Lung cancer	3	27.3 %
	Brain cancer	1	9.1 %
	Cholangiocarcinoma	1	9.1 %
	Colorectal cancer	4	36.4 %
	Prostate cancer	1	9.1 %
	Kidney cancer	1	9.1 %

The proportion of cancers discovered following the paraclinical investigations was 12%. In patients with newly diagnosed neoplasia, we observed the high incidence

of colorectal cancer (33.3%), lung cancer (25%), and cervical cancer (16.6%).

By performing the full extension assessment of the malignancy, we found that 40% of cancer patients were showing metastases. Although the proportion of cases with disseminated cancer was higher in the group with previously diagnosed cancer, it was not a statistically significant difference ($p = 0.288$).

Concerning the specific oncological treatments that could determine the occurrence of DVT in our study, 23.07% of cancer patients underwent surgery and radiotherapy, 30.07% - surgery and chemotherapy and 46.15% - surgery and both radio- and chemotherapy.

The established treatment strictly individualized according to the pre-existing comorbidities, the location of DVT, the presence of associated pulmonary embolism, hemodynamic status, hematological balance, the existence of a history of neoplasia and the presence of metastases followed one of these pathways: unfractionated heparin (65 cases), low molecular weight heparin (23 cases) and thrombolysis + subsequent heparin therapy (12 cases).

DVT of the popliteal vein was significantly associated with the need for urgent thrombolysis (performed exclusively in patients with DVT complicated with PE) (p=0.015). The effectiveness of the treatment was monitored during hospitalization and at discharge through venous doppler ultrasound, in order to assess the resumption of blood flow. Moreover, we recorded no fatalities during hospitalization or at the follow-up performed one month after discharge.

DISCUSSION

As we mentioned above, cancer patients are generally associated with a hypercoagulable state, as they usually have several associated abnormalities that are influencing each component of Virchow's triad (stasis of blood flow, endothelial injury, and hypercoagulability), thus leading to an enhanced prothrombotic activity. The cancer-associated thrombosis is a general term that covers a plethora of mechanisms and pathways involved in the imbalance between pro- and anticoagulant elements. It is noteworthy that the various data cited in literature regarding the prevalence or outcome of DVT in cancer patients are related to multiple variables (e.g., tumor site, stage, histological subtype, time since diagnosis, inclusion criteria and study design) (6). In the same manner, even if there is a systemic prothrombotic environment in all cancer types, the tumor location greatly influences the anatomical site of the thrombosis. Generally, DVT of the lower extremities or pelvic vein thrombosis are associated with colorectal cancer or other genito-urinary malignancies due to their proximity (8, 9) while a hepatocellular carcinoma determines particularly a portal or hepatic vein thrombosis (10), the latter can even migrate into the right cardiac chambers (11).

It is universally accepted that the incidence of DVT is not equivalent in different cancer types and, in fact, the rates of increased DVT in cancer patients may reflect the frequency of cancer within the general population and not necessarily some specific tumor-related prothrombotic effects. Nevertheless, multiple studies revealed that the highest incidence rates for DVT occur in certain adenocarcinomas of the lung and gastrointestinal tract (notably pancreas and colorectum) (6).

Usually, the cancer determines an up-regulation of the coagulation cascade. In

healthy individuals, the tissue factor (TF)- the initiator of the extrinsic clotting pathway- is expressed by sub-endothelial cells such as myocytes or interstitial cells. In many cancers, TF is abnormally expressed on tumoral cells' membrane, its presence being strongly correlated with a poor clinical outcome (high TNM stage, presence of metastases, decreased survivability) (9).

Very interestingly, TF expression not only induces prothrombotic effects *per se*, but it also accelerates cancer progression via clot formation, which are engulfing metastatic cells in the blood stream, allowing them to escape immune surveillance and to form circulatory islands of metastatic cells. In addition, TF upregulates intracellular signaling, acting via protease-activated receptor (PAR)-2, which is a promoter to key malignant processes including proliferation, migration, angiogenesis, and metastasis (9, 12). This mutual relationship rose the possibility to use the coagulation cascade as a potential therapeutic target in cancer patients. Multiple studies investigate the LMWH and direct oral anticoagulants (e.g., rivaroxaban) as well as direct TF inhibitors for their anticancer effects, showing beneficial effects on the survivability (13).

There is scarce data in literature concerning the overall effect of the gender in a cancer cohort and the potential risk of developing DVT. Some studies show that females are at a greater risk for VTE, while other authors failed to confirm this aspect (6, 14). The epidemiological data collected in our study regarding the etiology of DVT and gender distribution revealed similarities with other international studies, but also some particular aspects. Jara-Palomares *et al.* conducted one of the largest researches regarding paraneoplastic DVT, including 5864 patients. Of these, only 7.6% presented a neoplasm, a significantly lower percentage compared to our study. The same authors found that most common malignancies in men were lung cancer (25.9%) and prostate cancer (17.07%), while in women colorectal cancer (19.19%) and breast cancer were predominant (11.61%) (15). In contrast to these findings, in our study we observed a different distribution of cancer types according to sex, the colorectal cancer being the most prevalent among men, whilst cervical cancer was the leading etiology in the women. This pattern is multifactorial, being probably correlated with certain local specific risk factor, either hereditary, socio-economic, geographic, or dietary.

In a recent study, Rouzaud *et al.* found similar results to our research. Thus, the mean age was calculated to be 63.6 years, while the incidence of neoplasia was roughly the same in the two studies (29.6% vs. 25%) (16). Compared to our study, other data from literature have shown a lower incidence of neoplasia (9.71% and 7.5% respectively), but with a similar pattern of cancer distribution (17, 18).

A previous episode of DVT predicts well the occurrence of a new DVT episode. Cancer patients with a history of thrombosis are up to 7 times more prone to a DVT recurrence when compared to cancer patients without previous thrombotic events. Hettiarachchi *et al.* showed that 6.56% of patients had a recurrence of DVT, of which 7.96% had a neoplasm, a significantly lower percentage than those in our group (20.9%) (19). On the other hand, Prandoni *et al.* reported a significant association between recurrent thrombotic episodes and the subsequent diagnosis of malignancy (20).

Another interesting aspect from our study is regarding the significant association between the presence of metastases and the onset of PE (p= 0.048). This finding is in line with the results from several studies, which emphasize the association between advanced (stage III to IV) or metastatic cancer and the risk of PE (21, 22). This is due to the lower clot time and higher plasminogen activator inhibitor (PAI-1) level in patients with end-stage or metastatic cancer compared to those with stage I/II ($p < 0.05$), which could explain the higher risk of PE in these patients (23). Besides this, advanced stage cancers are associated with a poor-performance status in affected patients, the immobilization representing an important risk factor to the development of PE (6).

Anemia represents another well-known negative prognosis element not only in cancer patients (21), but also in patients with DVT (24). In our study, more than 30% of cases showed a variable degree of anemia, regardless of the presence of cancer. However, a very interesting issue was highlighted by Wang J *et al.* who demonstrated in a multivariate analysis that also an increased serum hemoglobin > 14 g/dL represents a high risk for the development of PE in lung cancer patients (OR, 2.10; 95% CI: 1.44-3.08, p = 0.03), explained by the stasis of blood flow due to higher blood viscosity (22). This controversial aspect was furtherly confirmed by the results from our study, a Hb>14 g/dL being significantly correlated with the occurrence of PE (p=0.05).

The proportion of DVT onset in our study was similar to that conducted by Carrier *et al.*: 67.4% had only DVT, 32.6% had only PE and 12.3% had a clinical presentation of both DVT and PE. However, the incidence of a neoplasm was only 3.9%, compared to 25% in our study. This may be due to a significantly larger number of included patients (854 cases) and the origin country of the study group- Canada- a developed country, where there is an improved accessibility and increased adherence to the medical system than in the North-Eastern Romania and, consequently, an increased probability for an early diagnosis (25).

This study presents certain limitations. First, the group size was relatively small – 100 patients with DVT, 25 of whom had a malignancy. In addition, DVT presence was assessed only in the lower extremities, without considering its occurrence in the upper limbs, pelvic veins, or inferior vena cava. Finally, some details regarding complete staging information of cancer were lacking due to various reasons, in addition to other aspects regarding its local extension or metastases that could influence the occurrence of DVT.

CONCLUSIONS

In conclusion, cancer patients represent a special category with a significantly higher risk of developing DVT as compared to non-cancer patients. This is due to a combination of tumor-related, treatment-related, and patient-related factors. Basically, the clinician should always maintain a certain degree of suspicion for thrombotic events when managing a cancer patient. In recent years there have been significant advances in the therapeutic approach of venous thrombosis and its most life-threatening complication-PE, by using the full spectrum antithrombotic medication, as stated in the last ESC guidelines (1).

The importance of the simultaneous cancer-DVT approach is confirmed by the

epidemiological data: the prevalence of paraneoplastic DVT in our group was 25%, with the proportion of incidentally discovered cancer in patients admitted for DVT being a worrying 12%. These results confirm the symbiotic relationship between these two pathologies, the specific incidence of DVT in cancer patients and vice versa being likely underestimated in the general population.

CONFLICT OF INTERESTS AND FUNDING

The authors declare that there is no conflict of interest and they received no specific funding regarding this scientific research.

NEWS

HIGH RIDING JUGULAR BULB - IMAGING EXAMINATION

High riding jugular bulb is a condition which appears when the roof of the jugular bulb extends superiorly in the petrous temporal bone than usual. The transverse level above which a jugular bulb is considered high riding has been variably defined as the following: floor of the internal auditory canal, 2 mm below the floor of the internal acoustic meatus, inferior rim of the round window niche or basal turn of the cochlea. Depending on the definition, the prevalence in different studies varies between 6 and 34%. The jugular vein bulb is almost always larger than the contralateral bulb. The associated enlargement of the jugular foramen can simulate a mass lesion on non-contrast-enhanced computed tomography (CT), although the diagnosis is made easily on contrast-enhanced CT or flow-sensitive magnetic resonance imaging (MRI). The sigmoid plate normally separates the jugular bulb from the hypotympanum of middle ear. This can only be appreciated on thin slice bone algorithm CT and is too thin to appreciate on MRI. If the sigmoid plate is deficient, the bulb protrudes into the middle ear and is known as a dehiscent jugular bulb, a common cause of a retrotympanic vascular mass. (Deng F, Gaillard F, *et al.* High riding jugular bulb. https://radiopaedia.org/articles/high-riding-jugular-bulb).

FUNCTIONAL HINDRANCE, COMORBID DEPRESSION AND EARLY DEVELOPMENT OF RESTRICTIVE LUNG DISEASE ARE LINKED TO ANKYLOSING SPONDYLITIS PATIENTS' WITHDRAWAL FROM THE WORKFORCE

FUNCTIONAL HINDRANCE, COMORBID DEPRESSION AND EARLY DEVELOPMENT OF RESTRICTIVE LUNG DISEASE ARE LINKED TO ANKYLOSING SPONDYLITIS PATIENTS' WITHDRAWAL FROM THE WORKFORCE (Abstract): Ankylosing spondylitis (AS) is a debilitating inflammatory rheumatic condition that has been associated with young patients' early retirement from the workforce. The present study aimed to examine the characteristics of professionally active patients with AS who were applying for work disability. **Material and methods:** We conducted a prospective observational study on working age patients with AS. The inclusion criteria were confirmed AS diagnosis, professionally active status, and stable treatment for at least 6 months. We assessed functional impairment using BASFI (Bath Ankylosing Spondylitis Functional Index). **Results:** The study group included 114 patients with AS. Functional hindrance (based on BASFI scores) was a major factor leading to work disability. Work impairment was more frequent in male patients, yet females were the only ones to retire from the workforce in the first 5 years of illness. We obtained statistically significant results regarding the association between work disability and restrictive lung disease as well as depression. Moreover, the relationship with restrictive lung disease remained statistically significant in subjects under 40 years of age as well as in the subgroup with a disease duration under 10 years. **Conclusions:** Our results indicate that, together with functional impairment, comorbid depression and an early development of restrictive lung disease may impact the work status of AS patients. Further longitudinal studies are needed to define and monitor the factors that lead to work disability in AS.
Keywords: ANKYLOSING SPONDYLITIS, DISABILITY, RESTRICTIVE LUNG DISEASE, DEPRESSION, OBESITY.

Ankylosing spondylitis (AS) is a chronic inflammatory rheumatic condition that has been associated with a notable economic burden on the health system (1, 2). Importantly, the onset of AS most frequently occurs in young working-age patients, frequently causing them to retire due to disease-related manifestations (3).

As the disease progresses, patients may develop potentially severe extra-articular manifestations (uveitis, kidney disease, cardiopulmonary or neurological involvement), spinal restriction and deformity, all leading to significant physical disability and decreased quality of life (4-6). Together with pain and fatigue, different aspects of AS-related functional impairment have been shown to demonstrate strong relationships with absenteeism and early withdrawal from the workforce (5-9).

The present study aimed to analyze the features of professionally active patients with AS who were applying for work disability. Secondary objectives included the characterization of relationships between the factors contributing to subjects' functional hindrance and work abandonment.

MATERIAL AND METHODS

We conducted a prospective observational study on working-age AS subjects who were either hospitalized or were referred to our department as outpatients. The inclusion criteria were confirmed AS diagnosis (according to the New York criteria), working age according to the local legislation, professionally active status, and stable treatment for at least 6 months. We excluded patients who were not professionally active (patients who had never worked, were already receiving work disability benefits for either AS or comorbidities, or had retired due to other reasons), persons who worked under special conditions, as well as subjects who had incomplete data.

We assessed disease activity using BASDAI (Bath Ankylosing Spondylitis Disease Activity Index) and ASDAS scores (Ankylosing Spondylitis Disease Activity Score). We evaluated the patients' functional hindrance using BASFI (Bath Ankylosing Spondylitis Functional Index). Certain characteristics such as HLA-B*27 positivity (Human Leukocyte Antigen), disease duration, treatment, comorbidities, and BMI (Body Mass Index) were taken from the patients' files. Walking impairment was defined as the inability to walk without support.

The statistical analysis of the data was performed using IBM *SPSS Statistics version 23.0* for Windows. Depending on variable distribution, we presented the descriptive analysis as Mean ± SD (Standard Deviation) or Median : IQR (Interquartile Range). Crosstabulations were analyzed using X^2 or Fisher's exact test (where the proportion of expected frequencies less than 5 was more than 20%, we chose the Fisher test).When comparing numeric values between different subgroups, we performed either parametric (student t-test) or non-parametric tests (Mann-Whitney U test) according to variable distribution. The statistical significance threshold was set at $p \leq 0.05$.

RESULTS

We examined 167 consecutive patients who fulfilled the inclusion criteria for the present study. Following the elimination of subjects who met the exclusion criteria, the final group consisted of 114 patients aged between 23 and 56 years with a mean disease duration of 14.88 years, male subject being more numerous than females (M:F=2.7:1) (tab. I).

More than half of the study group applied for work disability (60.5%), whereas 39.5% chose to remain professionally active. Work impairment was significantly more prevalent in male patients (67.5% *vs.* 41.9%; X^2, p=0.013) and those residing in rural areas (72.6% *vs.* 46.2%; X^2, p=0.004). We found notable associations between work disability and disease duration as well

as age (t-test; p=0.004, p<0.001). Nevertheless, age and duration of symptoms did not vary significantly according to gender (t-test; p=0.123, p=0.143) or the area of residence (t-test; p=0.118, p=0.891).

TABLE I

Characteristics of the study group

Parameter	Characteristics Number (%); Minimum-Maximum (Mean±SD/Median: IQR)		
Age (years)	23-56 (46.82±7.51)		
Gender	Male	83 (72.8%)	
	Female	31 (27.2%)	
Area of residence	Urban	52 (45.6%)	
	Rural	62 (54.4%)	
HLA-B*27	Positive	109 (95.6%)	
	Negative	5 (4.4%)	
Disease duration	2-30 (14.88±5.95)		
Professional activity	Applying for work disability	69 (60.5%)	
	Not applying for work disability	45 (39.5%)	
Smoking	Smokers	29 (25.4%)	
	Non-smokers	85 (74.6%)	
BMI (kg/m^2)	16.61-38.05 (27.02±4.79)		
Comorbidities and disease-related complications	Uveitis	8 (7.0%)	
	Chronic kidney disease	4 (3.5%)	
	Depression	10 (8.8%)	
	Diabetes mellitus	9 (7.9%)	
	Cardiovascular involvement	Arterial hypertension	33 (28.9%)
		Ischemic heart disease	1 (0.9%)
		Heart failure	2 (1.8%)
		Rhythm/conduction abnormalities	1 (0.9%)
	Respiratory involvement	Pulmonary fibrosis	3 (2.6%)
		Restrictive lung disease	47 (41.2%)
	Digestive involvement	Gastritis/Ulcer	12 (0.5%)
		Crohn's disease	1 (0.9%)
CRP (mg/l)	0.10-123.30 (15.21±22.35)		
ESR (mm/1h)	2.00-107.00 (24.51±18.85)		
BASDAI	0.40-8.40 (3.55:1.48-6.1)		
ASDAS-CRP	1.00-6.00 (2.75±1.19)		
ASDAS-ESR	0.77-5.55 (2.69±1.25)		
BASFI	0.50-9.60 (5.25:2.40-7.1)		
Walking impairment	2 (1.8%)		
Treatment	NSAIDs	69 (79.3%)	
	Sulfasalazine	12 (10.5%)	
	Biologics	Total	46 (40.3%)
		TNF inhibitors	42 (36.8%)
		IL-17 inhibitor	4 (3.5%)

Most patients had tested positive for HLA-B*27 (95.6%) (tab. I). However, HLA-B*27 positivity, although more prevalent, was not significantly associated with work disability in our study group (61.5% *vs.* 40%; Fisher's exact test, p=0.382).

ESR (Erythrocyte Sedimentation Rate) and CRP (C-reactive protein) levels, ASDAS-ESR as well as ASDAS-CRP did not differ significantly in patients with work impairment compared to those who remained professionally active (t-test; p=0.293, p=0.206, p=0.995, p=0.927).

Restrictive lung disease (78.7% *vs.* 47.8%) and depression (90% *vs.* 57.7%) were significantly associated with work impairment (X^2, p=0.001 and p=0.046), while uveitis, diabetes, renal and cardiovascular manifestations did not show a notable relationship with disability (p>0.05). Work impairment was also more likely to be found in the subgroup presenting with gastritis and gastroduodenal ulcers (90% *vs.* 57.7%; X^2, p=0.003).

Whereas BASDAI values did not vary significantly with respect to work disability (Mann-Whitney, p=0.467), we found significantly higher BASFI scores (Mann-Whitney, p<0.001) in patients who expressed the intent to retire from the workforce (6.3:3.05-7.45) compared to professionally active individuals (3.1:1.90-5.70) (fig. 1).

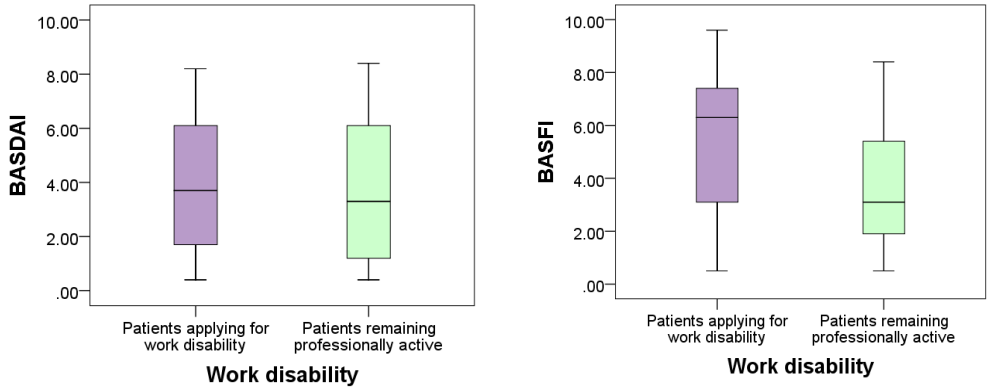

Fig. 1. BASDAI and BASFI values with respect to work disability.

Certain actions such as looking over the shoulder, reaching up to high shelves and picking up an object from the floor were found to be impossible (scored as 10) in patients with work disability more often than in professionally active subjects (X^2, p=0.034, p=0.042 and p=0.005).

Total BASFI scores over 5 were more likely to be noted in the work impairment subgroup (75.9% *vs.* 44.6%; X^2, p=0.001). Similarly, scores higher than 5 were found more frequently in the work disability category with respect to reduced mobility in the cervical spine (78.8% *vs.* 35.4%; X^2, p=0.001), difficulty picking up an object off the floor (75% *vs.* 46.6%; X^2, p=0.002) and putting on socks (75.9% *vs.* 44.6%; X^2, p=0.001), as well as greater effort performing physically demanding actions (73.5% *vs.* 41.3%; X^2, p=0.006) or common daily activities (70.6% *vs.* 45.7%; X^2, p=0.008), climbing stairs (70% *vs.* 50%; X^2, p=0.029), reaching up to high shelves (75% *vs.* 44.4%; X^2, p=0.001), getting up from the floor (70.8% *vs.* 46.9%; X^2, p=0.010), and standing up from an armless chair

without help (76.7% *vs.* 40.7%; X^2, p=0.006). While scores over 5 remained more prevalent in subjects applying for work disability (67.9% *vs.* 54.1%), results did not reach statistical significance with regard to standing unsupported (Fisher's exact test, p=0.179). However, scores higher than 4 were more frequent in the subgroup with work impairment (69.2% *vs.* 49%; X^2, p=0.029).

Young patients (≤ 40 years old) who applied for work disability did not demonstrate higher BASFI scores (total scores as well as for each question) compared to professionally active patients in the same age group (Mann-Whitney, p>0.05). Nevertheless, the presence of restrictive lung disease as well as depression requiring chronic treatment showed notable associations with work impairment (p<0.001 and p=0.030). In this age category, we did not identify a connection between gender and work disability (Fisher's exact test, p=0.376), despite the latter being more frequent in female patients (44.4% *vs.* 23.1%).

In the subgroup with a disease duration under 5 years, work disability was only found in female patients. However, these results were not statistically significant (Fisher's exact test, p=0.464). The presence of restrictive lung disease was significantly associated with work impairment in patients with a disease duration under 10 years (100% *vs.* 26.3%; X^2, p<0.001) but not in those displaying symptoms for over a decade. In these cases, BASFI remained the most notable factor linked to the patients' withdrawal from the workforce (6.3:3-7.57 *vs.* 3.7:1.9-6.2; Mann-Whitney, p=0.008).

Neither underweight nor excess weight were significantly more frequent in patients with disability. However, obese subjects demonstrated increased median BASFI scores compared to eutrophic and underweight individuals (6.15:4.37-7.17 *vs.* 4.05:2.00-6.95; Mann-Whitney, p=0.022). Moreover, these patients had higher difficulty bending down to put on socks (6:4-8.25 *vs.* 3:2-7; Mann-Whitney, p=0.002) or to pick up an object of the ground (6:4-8 *vs.* 4:2-7.75; Mann-Whitney, p=0.011), standing up from an armless chair (4.5:3-6 *vs.* 3:1-6; Mann-Whitney, p=0.038), getting up from the floor without support (6.5:4.75-8 *vs.* 4.5:2-8; Mann-Whitney, p=0.022), as well as greater effort performing daily activities (6:4.75-7 *vs.* 5:2.25-7; Mann-Whitney, p=0.041) and physically demanding actions (6:5-8 *vs.* 5:2-7; Mann-Whitney, p=0.026).

Whereas NSAIDs and Sulfasalazine did not demonstrate a notable connection to work disability, patients under biological therapy were more likely to retire (71.7% *vs.* 52.9%; X^2, p=0.044). Moreover, there was no association with older age in this subgroup (47.37±6.88 *vs.* 46.87±8.44 years; t-test, p=0.728). Although the mean disease duration did not differ between patients with work disability compared to the rest of the subjects in the group treated with biologics (15.30±5.77 years *vs.* 14.59±6.07 years; t-test, p=0.526), individuals who expressed their intent to retire were more likely to exhibit a disease duration of over 10 years (78.4% *vs.* 44.4%; X^2, p=0.043) as well as restrictive lung disease (94.1% *vs.* 58.6%, X^2, p=0.010).

Patient-reported fatigue was not significantly associated with the retirement from the workforce in our study group irrespective of age, gender, or disease duration (Mann-Whitney, p>0.05). Nonetheless, work disability was associated with more severe neck, back and hip pain in female patients (7:3.5-8 in women with work disa-

bility *vs.* 2:1-7 in women who remained professionally active; Mann-Whitney, p=0.028) and in those with a disease duration under 10 years (6:4-8 in patients with work disability *vs.* 2:1-4.25 in persons in the same subgroup who remained professionally active; Mann-Whitney, p=0.009).

DISCUSSION

AS remains a debilitating disease despite the recent advancements in therapeutic management. Importantly, BASFI continues to be a reliable indicator of functional hindrance and correlates with absenteeism and early retirement from the workforce in AS (10). Similar to our findings, previously published research states that older age and longer disease duration may impact both patient-reported functional impairment as well as their work status (3, 11, 12).

Our results showed a statistically significant relationship between work disability and male gender, the latter demonstrating a clear predominance in the study group. The currently available literature reports discrepant findings regarding the link between gender and work capacity in AS (13). A Swedish study indicated that the prevalence of work impairment could be reduced in women with AS (14). Moreover, it has been shown that female patients may exhibit higher rates of work abandonment during the first years of illness (15). We obtained similar results in this respect, only women with a disease duration under 5 years applying for work disability.

In AS, restrictive lung disease can influence certain functional parameters as well as the patients' quality of life (4, 16). We obtained statistically significant results regarding the association between restrictive lung disease and work disability. Moreover, this relationship remained statistically significant in subjects under 40 years of age as well as in the subgroup with a shorter disease duration (under 10 years). In contrast, restrictive lung disease was not associated with work impairment the group exhibiting symptoms for more than a decade where work abandonment was rather correlated with impaired functionality.

The relationship between depression and absenteeism in AS has been studied previously, research reporting discrepant results in this respect (3,17-19). Depression may be frequent and has been correlated with higher rates of work abandonment in AS (20-22). A recent study found a significant association between absenteeism and the mental component of SF-36 (the 36-item Short Form health survey) (19). Comorbid depression was linked to work disability in our study group including in patients under 40 years of age. These data further support the inclusion of psychologists and psychiatrists in the multidisciplinary teams that manage the care of AS patients (17-19).

Pain, fatigue and disease activity have been shown to impact AS patients' presenteeism, absenteeism and early retirement (5-7). Disease activity and fatigue were not associated with work disability in our group, while back pain was only linked to work impairment in women and in persons with a shorter disease duration.

Contrary to the results described in other studies that highlight the improvement of functionality under biological therapy, we obtained a high rate of work disability among these patients compared to those receiving conventional treatment (23-27). Nonetheless, the subjects who were treated with biologics and expressed their intent to retire were more likely to exhibit a disease duration of over 10 years and restrictive lung disease compared to their profession-

ally active counterparts, thus explaining the discrepancy. Additionally, the differences between countries regarding the inclusion criteria for biological therapy (BASDAI and ASDAS scores, inflammatory marker levels and other factors) may result in patients starting the treatment either earlier or later in evolution.

Obesity has been shown to be more frequent in persons with axial SpA compared to the general population and may influence clinical outcomes, particularly patients' response to anti-TNF therapy (28, 29). Interestingly, it has been stated that excess weight may play a role in the development of structural damage and radiographic progression. Moreover, the expression of inflammatory adipokines is increased in obese patients and it has been suggested that leptin and resistin promote new bone formation in AS (30-33). The currently available literature reports inconsistent results regarding the link between obesity and the burden of symptoms, BASFI values and work disability in AS (34, 35). Whereas body composition was not significantly associated with work abandonment, obesity was associated with functional disability in our study group, impacting such actions as bending down, standing up from an armless chair and getting up from the floor. Moreover, obese patients reported having higher difficulty performing daily activities and physically demanding actions, Thus, albeit without a direct relationship between obesity and early retirement, our results indicate that AS patients' functional impairment may be aggravated by excess weight.

CONCLUSIONS

Work impairment continues to be a major issue in AS. We aimed to analyze the characteristics of professionally active patients who were applying for work disability, our results indicating that functional hindrance is one of the main contributors to the patients' early retirement in these cases. HLA-*B27 positivity, fatigue, disease activity, and most comorbidities or complications did not exhibit significant relationships with work impairment in our study cohort. Nonetheless, restrictive lung disease and comorbid depression were significantly correlated with AS patients' work abandonment. Moreover, the relationship with restrictive lung disease remained statistically significant in subjects under 40 years of age as well as in the subgroup with a disease duration under 10 years. Additionally, obesity has been found to contribute to the aggravation of functional impairment in working age AS patients. Further longitudinal studies are needed to define and monitor the factors that may lead to AS patients' functional hindrance and work disability.

CONFLICT OF INTEREST AND FUNDING

ANTIPLATELET THERAPY AND INFLAMMATORY STATUS ASSOCIATED WITH INTRA-STENT RESTENOSIS AFTER PERCUTANEOUS CORONARY INTERVENTION (Abstract): The present study analyzed the existence and quantification of inflammatory status and antiplatelet medication associated with intra-stent restenosis (ISR) in coronary artery disease (CAD) patients after percutaneous coronary intervention (PCI). **Material and methods**: an observational cross-sectional study was conducted in a high-volume PCI centre over a 2-year period. A total of 235 consecutive patients diagnosed with angina or acute coronary syndrome treated by PCI were included in the study. Diagnosis of ISR was documented by coronary angiography and the patients were divided into groups (with and without ISR). All patients underwent clinical and laboratory examination, the administration of antiplatelet medication and the type of drug administered to each patient. **Results**: The mean time until ISR was 33 ± 34 weeks. The lower use of single or dual antiplatelet therapy was associated with increased risk of ISR. Aspirin alone [risk ratio (RR)=1.13; 95% confidence interval (95% CI): 0.882-1.462], clopidogrel alone (RR = 1.41; 95% CI: 0.879- 0.323), ticagrelor alone (RR = 1.98; 95% CI: 1.746-2.252) or dual antiplatelet therapy (DAPT) (RR = 0.82; 95% CI: 0.637-1.065) had a significant role in estimating the risk for ISR. Bare-metal stents (BMS) presented an associated risk of ISR higher as compared to drug-eluting stents (DES) (0.88 *vs.* 0.74). **Conclusions**: Inflammatory status is associated with ISR; the type of stent used, time to ISR and antiplatelet medication were found to be associated with ISR.
Keywords: ANTIPLATELET THERAPY, INTRASTENT RESTENOSIS, PERCUTANEOUS CORONARY INTERVENTION.

Cardiovascular diseases (CVD) remain the leading cause of death worldwide and atherosclerotic coronary artery disease (CAD) are mainly involved in this patholo-

gy (1). After percutaneous coronary intervention (PCI) patients are still at risk of developing new stenosis and in some cases intra-stent restenosis (ISR). The introduction of coronary drug-eluting stents (DES) has substantially decreased the incidence and prevalence of ISR, but it is still encountered in 5 to 15% of PCI procedures (2-5). The increasing use of percutaneous revascularization in complex and long lesions has likely contributed to the continued episodes of restenosis and the need for repeated interventions.

Despite the safety and efficacy of DES, bare-metal stents (BMS) are still used (6). The incidence of ISR is also significant because inflammatory responses after PCI lead to abnormal neointimal healing and generate an increased risk for unfavorable outcomes (7, 8). Such data suggest that the type of stent is only one factor to consider when searching for additional promoters of ISR. Thus, the aim of the current study is to analyze the risks of ISR associated with the administration of antiplatelet medication after PCI.

MATERIAL AND METHODS

Patient selection and study design: An observational, cross-sectional, over a 2-year period study was conducted and included 235 patients diagnosed with angina pectoris or acute coronary syndrome (myocardial infarction with or without ST-segment elevation) with intra-stent restenosis documented by coronary angiography hospitalized in the Cardiology Clinic of the "Prof. Dr. George I. M. Georgescu" Institute of Cardiovascular Diseases Iasi. Our population was divided into 2 groups: the ISR group (119 patients) that presented ISR documented by coronary angiography (> 50% stenosis of a previously stented segment) and the control group (116 patients) without angiographic ISR, but with different other culprit lesions or no significant angiographic stenosis.

The selection of patients was made on the following inclusion criteria: age over 18 years; diagnosis of angina pectoris/acute myocardial infarction with or without ST-segment elevation treated by PCI with stent implantation at the time of study; free informed consent. The exclusion criteria were refusal of treatment; failure to report or abandon treatment; patients who belonged to vulnerable categories, such as coma patients or pregnant women. The study was approved by the "Grigore T. Popa" University of Medicine and Pharmacy Iasi Research Ethics Committee and all subjects had initially agreed and signed an informed consent to take part in this study.

Clinical and paraclinical characteristics: To prevent the onset of ISR after PCI, all patients underwent antiplatelet therapy according to the guidelines. Initially, all stent patients received two antiplatelet agents. The duration of double antiplatelet treatment varied according to diagnosis at the time of initial presentation; type of DES/BMS implanted stent; the presence of medical conditions or special situations that required individualization of the duration of antiplatelet treatment (hemorrhagic complications, combination of oral anticoagulant treatment, surgery that required stopping one or even both antiplatelet drugs). At the end of the treatment period in double combination, the patients most frequently received the recommendation to continue with a single antiplatelet agent, aspirin being the most frequently used. Regarding the double combination, there were patients who received aspirin with ticagrelor and aspirin with clopidogrel. Most commonly, however, the combination of aspirin and clopidogrel has been used.

Diagnosis of ISR was documented by coronary angiography in patients with suggestive coronary symptoms and ischemic changes in non-invasive or invasive paraclinical investigations. Depending on the drug used, a significant difference in the rate of intra-stent restenosis was observed.

Statistical analysis: Data analysis was performed using *SPSS version 23.0* (Statistical Package for the Social Sciences; IBM Corp.). Comparison between the 2 groups of patients was performed using *Chi-square* test for the categorical data and one-way *ANOVA* and *Student's t-test* for continuous data. To estimate the strength of the association between treatments and outcome (with or without ISR) relative risk (RR) with 95% confidence interval (CI) was used in the statistical analysis of the data. A p value < 0.05 was considered statistically significant.

RESULTS

The mean age of the patients was 61.84 ± 11.12 years (63.08 years, ISR group; 60.57 years, non-ISR group; p=0.084). The male was 83(70%) in ISR group and 81(70%) in non-ISR group(p<0.989) and the repartition of female was 36(30%) in ISR group and 81(70%) in the other group(p<0.522). The CRP > 2 mg/dL was significantly higher in the ISR group: 94(87%) *vs*. 83(77.6%, p<0.05).

In our study the antiplatelet treatment was composed of single aspirin, single ticagrelor, single clopidogrel alone and double therapy (DAPT). As stated in first table, only aspirin was administered in 51.3% of ISR group and 44.8% of non-ISR group (p = 0.324). In the ISR group, regarding DES patients, aspirin was given in 53.1% and in BMS patients in 50.6%; similar percentages were identified in the non-ISR group (41.7% in DES patients and 48.2% in BMS patients). Ticagrelor and clopidogrel were not so frequently administered, with 0.8% in ISR group and 0% in non-ISR group for ticagrelor (p = 0.322) and 4.2% in ISR group and 1.7% in the non-ISR group for clopidogrel (p = 0.264). Double combination was used in 43.7% of ISR patients and 53.4% of non-ISR patients (p = 0.135). In the ISR group, regarding DES patients, double combination was given in 43.8% while in BMS patients in 43.7%; higher percentages were identified in the non-ISR group (55.0% in DES patients and 51.8% in BMS patients).

Furthermore, our study aimed to identify if there is a different relative risk (RR) regarding ISR depending on the drug and type of stent used (tab. II). Therefore, single aspirin regime has a relatively 1.13-fold increased risk of ISR (RR = 1.13; 95% CI: 0.882-1.462). In patients with DES the risk of restenosis is 1.34 times higher (RR = 1.34; 95% CI: 0.771-2.362) while in patients with BMS is 1.03 (RR = 1.03; 95% CI: 0.798-1.350). Aspirin was part of the adjuvant treatment in both groups, with a higher proportion in ISR group (51.3%) especially after the implantation of DES (53.1%). In our study, ticagrelor treatment has been used only in patients with DES, identifying a risk of ISR approximately 3-fold higher (RR = 2.93; 95% CI: 2.206-3.907). Clopidogrel has been used in both groups in varying proportions and is associated with a 1.68-fold increased risk of ISR in patients with BMS (RR = 1.68; 95% CI: 1.466-1.932) and 55% higher in patients with DES (RR = 1.55; 95% CI: 1.331-1.809).

In patients with BMS, double antiplatelet therapy is noted as a protective factor (RR = 0.88; 95% CI: 0.673-1.150), a result that has been also noticed in patients with DES (RR = 0.73; 95% CI: 0.423-1.312). Overall, the results indicate that double antiplatelet combination involves a lower risk of ISR (RR = 0.82; 95% CI: 0.637-1.065).

TABLE I

ISR, intra-stent restenosis; DES, drug-eluting stents; BMS, bare-metal stents

Assessing the presence of restenosis events in patients that went PCI and the type of drugs used in our patients, BMS implantation was directly linked to restenosis events, considering the time related to ISR, in comparison with DES implantation, regardless of the type of antiplatelet therapy. Furthermore, late ISR in DES patients were observed only in those patients with a double combination of drugs (figs. 1-4). Moreover, the mean time until ISR was 33 ± 34 weeks.

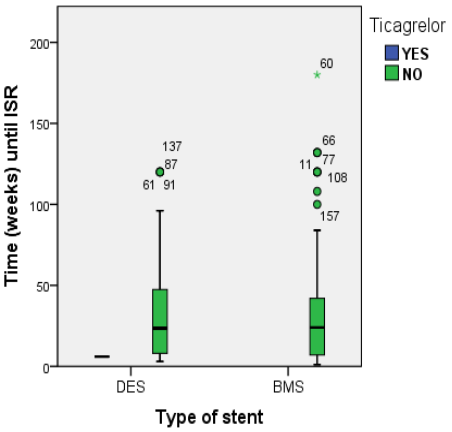

Fig. 2. Time until ISR depending on type of stent and single ticagrelor

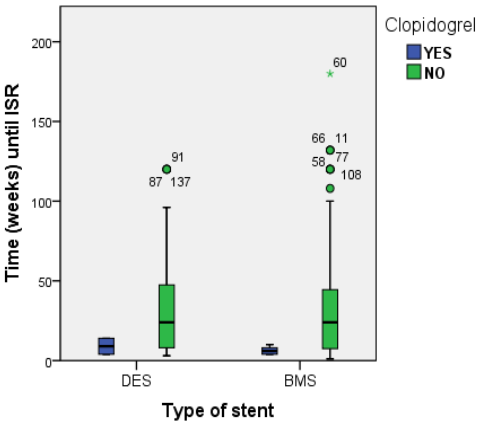

Fig. 3. Time until ISR depending on type of stent and single clopidogrel

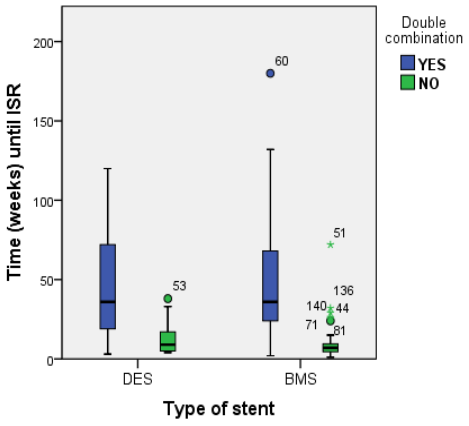

Fig. 4. Time until ISR depending on type of stent and double antiplatelet therapy

DISCUSSION

The main finding of the present study is that ISR in patients following PCI is associated with the type of antiplatelet medication and the type of stent. Patients were screened for clinical and paraclinical characteristics, coronary-lesion related factors and stent-related factors. Studies are con-

troversial concerning the risk of ISR in patients after PCI, thus further research in larger cohort studies is still encouraged.

An important aspect derived from our retrospective study is related to the time until ISR appear in our cohort of patients. The mean time until ISR was 33 ± 34 weeks (approximate 231 ± 238 days). In practice, because of differing pathophysiology and risk factors it is useful to dichotomize events into two major categories (9): early ISR is defined as thrombosis within the first 30 days after PCI and late ISR occurs beyond 30 days. According to RESTART investigators (9), early ISR is more common, accounting for 50 to 70% of all cases depending on the overall time frame of reference (10). In our study, according to this classification, late ISR was more common that early ISR meaning that other risk factors are associated with ISR (11-14). Moreover, in our cohort, serum C-reactive protein levels are statistically significant for ISR.

Recently, important progress has been made to reduce the incidence of ISR. Large-scale registries show that with contemporary antithrombotic therapies and modern generation of DES stents the rate of early ISR is low (15). Furthermore, a recent systematic review of randomized trials with DES reporting results at 9–12 months has shown a median incidence of ISR of 0.61% (16). The advantages of DES over BMS in preventing ISR have been proven by literature and are also confirmed in our study. A systematic review concerning the treatment of coronary ISR confirmed a higher rate of ISR after BMS implantation (20-35%) *vs.* DES implantation (5-10%) (17). In addition, Zbinden *et al.* showed a higher risk of ISR in segments with a BMS compared to segments with a DES (5.4% *vs.* 0.76% after 2 years) in 2,278 patients (18). Moreover, randomized trial data in the setting of stent implantation for acute myocardial infarction suggests the reduction of early ST segment with polymer coated *vs.* BMS (19). In our analysis, BMS presented an increased risk of ISR as compared to DES (RR 0.88 *vs*. 0.74 in case of dual antiplatelet therapy).

The key for ISR prevention is the prescription of dual antiplatelet therapy (DAPT) after PCI with an appropriate duration. In patients presenting with acute coronary syndrome, the cardiovascular risk remains substantially elevated beyond the first year, even if successful revascularization has been achieved (20). In this setting, intensified antiplatelet therapy on top of aspirin has been shown to be an effective therapeutic strategy to prevent recurrent ischemic events. In our study DAPT was the most administered scheme in non-ISR group (53.4%) and second scheme (43.7%) in ISR group. Also, the relative risk of ISR was the lowest in DAPT group (0.82; 95% CI: 0.637-1.065) in comparison with aspirin alone (RR = 1.13; 95% CI: 0.882-1.462), clopidogrel alone (RR = 1.41; 95% CI: 0.879-2.323) or ticagrelor alone (RR = 1.98; 95% CI: 1.746-2.252). Single aspirin regime has a relatively 1.13-fold increased risk of ISR. This can be explained by the fact that patients were late diagnosed with ISR when patients had already switched from the DAPT regimen to a single antiplatelet drug. According to the DAPT trial (21), a DAPT regimen is more effective than aspirin monotherapy in reducing the incidence of very late stent thrombosis. Moreover, it suggests that DAPT mitigates the risk of stent thrombosis across the whole spectrum from acute to very late events. From another point of view, although DAPT can reduce the risk of stent thrombosis (22), it had no impact on the

ISR risk, thus raising a question over the role of initial thrombus formation in the subsequent development of neointima (23). The lack of relationship on clinical or imaging endpoints between platelet inhibition and neointima formation was subsequently confirmed with other antiplatelet agents (24). The newer P2Y12 inhibitors, prasugrel and ticagrelor, have proven more efficacious than clopidogrel in the prevention of early and late stent thrombosis in patients with ACS, even with higher bleeding liability (25, 26). In our study ticagrelor was not very frequently used due to local socio-economic reasons at the study time.

Our retrospective study has several limitations. Firstly, the small sample size may overestimate the magnitude of an association or even induce false-positive results. Secondly, our patients were not divided into acute or chronic angina subgroups. Also, the study reported an increased number of BMS implantations, and the socio-economic factor had a high influence in the treatment decision on the baseline of CAD.

CONCLUSIONS

Inflammatory status is associated with ISR. Further on, the type of stent used, time to ISR, but especially antiplatelet medication was found to be associated, to varying degrees, with ISR in patients following PCI. Therefore, a close follow-up should be targeted in these patients.

VARIATIONS OF THE EFFICIENCY OF BIOLOGICAL THERAPY IN VULGAR PSORIASIS (Abstract): With the rapid understanding of the pathogenesis of psoriasis, the number of treatment options available for moderate to severe form has also increased. In this paper, we focus on the efficacy and safety profile of biological products in patients with psoriasis. In addition, we discuss the impact of biologics on comorbidities caused by psoriasis, considering several factors associated with the patient and the condition, and aim to review therapeutic opportunities in terms of biologic therapies and their variety. **Material and methods:** A retrospective study that has as a sample a group of 113 patients diagnosed with psoriasis vulgaris, under investigation by the Dermato-Venerology Clinic at the "Sf. Spiridon" County Clinical Emergency Hospital Iași. All these patients are under biological therapy and were admitted to the clinic between 2017-2021. **Results:** Of the 113 patients proposed for the study, 63% were male (n = 71) and 37% female (n = 42). Of the total sample, the preponderance of the age range was that of the '> 40 years' range with a total of 85% (n = 96) consisting of 61 men and 35 women (p = 0.019, statistically significant result). **Conclusions:** With the introduction of new biological substances and the discontinuation of others, an update of biological substances in psoriasis is delayed. Understanding the benefits, risks and monitoring of patients with biologic therapies is becoming increasingly important for the dermatologist**.** **Keywords:** PSORIASIS, BIOLOGICAL THERAPY, THERAPEUTIC VARIETY.

Psoriasis is a chronic condition with several systemic and immune manifestations that affect over 125 million people worldwide (1). It is associated with multiple comorbidities, which may complicate the management of the condition for these patients (2, 3). With the rapid understanding of the pathogenesis of psoriasis, the number of treatment options available for moderate to severe form has also increased. Moreover, factors related to the patient and pathology must be considered when initiating biological treatment in clinical practice (3, 4). A variety of biological agents for the treatment of psoriasis are available today. However, characteristics such as rapid onset, long-term efficacy, safety profile and effects on comorbidities are different (5). A

better understanding of these characteristics leads to the correct individualized choice for the patient, resulting in greater persistence, longer drug survival, greater patient satisfaction and minimizing the impact of the disease (6). Randomized clinical trials provide important information on the safety and efficacy of biological agents, however, the data in these studies have no practical implications for personalized therapy for patients with psoriasis (7, 8).

Psoriatic arthritis is a progressive inflammatory arthritis present in up to 30% of patients with psoriasis, with a higher risk of more extensive psoriasis. Where possible, a single biologic should be used in the treatment of both psoriasis and psoriatic arthritis. Most of the currently available biological agents in psoriasis have been approved for the treatment of psoriatic arthritis with 2 exceptions: guselkumab and brodalumab (8, 9).

In this paper, we focus on the efficacy and safety profile of biologics in patients with psoriasis, including plaque psoriasis and psoriatic arthritis. In addition, we discuss the impact of biologics on comorbidities caused by psoriasis, considering several factors associated with the patient and the condition, and aim to review therapeutic opportunities in terms of biologic therapies and their variety.

MATERIAL AND METHODS

A retrospective study that has as a sample a group of 113 patients diagnosed with moderate, moderate-severe and severe form of psoriasis vulgaris, under investigation by the Dermato-Venerology Clinic at the “Sf. Spiridon” County Clinical Emergency Hospital Iași. All these patients are under biological therapy and were admitted to the clinic between 01/01/2017-31/05/2021. In establishing their profile, the following were taken into account: gender, age, which was subsequently divided into age ranges, associated pathologies, special conditions of psoriasis, current biological therapy and year of initiation, PASI score, DLQI at the initiation of current biological therapy and to the re-evaluation of the scores at present, the previous biological therapies (therapeutic switches), the number of their presentations per clinic (both day and continuous hospitalizations) in the interval proposed for the study. All patients included in the study signed their consent to the processing of personal data.

The modification of the PASI and DLQI score was used as a clinical marker of disease progression, the comparative values between the initial and current scores establishing the activity of the disease and the patient's response to treatment. Statistical analysis of patient data was processed in *SPSS Statistics version 17* and *Microsoft Excel*. In *SPSS*, t-test and χ^2 were used, as follows: $p < 0.05$, the statistical link is significant (S, 95% confidence); $p < 0.01$, the statistical link is significant (S, 99% confidence); $p < 0.001$, the statistical link is highly significant (HS, 99.9% confidence); $p > 0.05$, the statistical link is insignificant (NS).

RESULTS

A total of 113 clinically diagnosed and histopathologicaly confirmed patients with plaque psoriasis were enrolled. The gender distribution includes 42 female patients (37%) and 71 male patients (63%). From the total sample, it appears that with age, the cases of psoriasis increase, the preponderance of the age range being ’over 40 years' with a total of 85% (n = 96) consist-

ing of 61 men and 35 women. (p = 0.019, statistically significant result).

As a place of origin, 62% (n = 70) with 57% men and 43% women belong to the urban area and 38% are from the rural area (n = 43) with 72% men and 28% women. The number of men is higher in both urban and rural areas. (p= 0.00016 statistical link is highly significant). We can see that the predominance of patients in urban areas is predominant, a fact explained in accordance with the literature through a more open access to education, new and updated information, where a greater emphasis is placed on the physical aspect, this being an important element for the profession and for socialization.

From the point of view of special impairment, the touch of the nail, palms and soles, scalp, face, genital area and folds was considered, and we highlight the fact that 66% of patients (n = 75) have special impairment and 34% (n = 38) are without. The most common touch was the scalp with 37% (n = 52), followed by 29% (n = 41) nails, 13% (n = 19) palms and soles, 10% (n = 14) on the face, 6% (n = 9) inverted and 5% (n = 7) genital with a predominance of male involvement except genital - 71% (n = 5) were women and 29% (n = 2) men, a situation also found in a study by Burlando *et al*, published in October 2019 (9), (p = 0.0007 the statistical link is highly significant). While in classical literature we are shown the onset of lesions on traditional areas (lumbosacral, elbows, knees), today, in a new approach we can see that the most interested areas were the scalp, nails, palms and soles, either from the beginning or along the way.

Regarding the comorbidities of the patients, 31% have associated cardiovascular pathology (n = 53) and also 31% (n = 53) have metabolic damage, where the preponderance was male on all comorbidities (p = 0.049 significant). Let's not forget that the metabolic syndrome is closely related to the cardiovascular damage and that the association of psoriasis with these two conditions increases the risk of each disease by creating a vicious circle, a risk that not only endangers the quality of life but also the patient's vital prognosis. Being a chronic inflammatory disease with both skin and systemic damage, it becomes absolutely necessary to control its activity, which has the consequence of reducing cardiovascular and metabolic complications.

Referring to biological therapies, 59% of patients are in the first biological therapy (n = 67) of which 66% are men (n = 44) and 34% (n = 23) are women, 31% are in the first therapeutic switch (n = 35) of which 63% men (n = 22) and 37% (n = 13) women and 10% are at the 2nd therapeutic switch (n = 11) of which 55% men (n = 6) and 45% women (n = 5) (p = 0.0005 significant high).

In terms of current biologic therapy, 58% of patients are being treated with anti-TNF α agents (58%) of which 68% are men (n = 64) and 32% are women (n = 41) and 42% are anti-interleukin agents (n = 48) of which 56% men (n = 27) and 44% women (n = 21). Of the 46 patients with previous biologic therapies, 52% (n = 24) switched from an anti-TNF α therapy to an anti-TNF α agent, 40% (n = 18) switched from an anti- TNF α on anti-IL, 4% (n = 2) an anti-IL on anti-TNF α and 4% (n = 2) an anti-IL also on anti-IL.

In terms of severity, PASI at the time of initiation of current biological therapy had a score between '2-10' in 19 patients, between '11-20' in 30 of them, between '21-30' in 56 patients and 8 people had '> 30'

with a direct ratio proportional to severity in both men and women up to the range '21-30'. Most of those with '> 20' also had special impairments - (scalp, nails) with significantly higher PSSI and NAPSI scores. Regarding the current PASI, most of the patients had a significant improvement of the disease, 50 patients with PASI '<2' and 49 with a score between '2-10'. At the initial DLQI, the score was between '21-30' in a total of 66 patients (%) of whom 38 were men and 28 women. At the current DLQI, 43 patients are in the range '0-1' and 38 between '2-5' with a significantly higher ratio in favor of men, but at a score of '21-30' there is an increased ratio of the number of women (n = 8) compared to men.

TABLE I

Distribution of patients according to gender, provenance, special impairment, comorbidities and biological agent

Parameter		Total	Lot 1	Lot 2	P
			Male	Female	
Gender		113(100%)	71(63%)	42(37%)	0.0019
Provenance	urban	70(62%)	40(57%)	30(43%)	0.00016
	rural	43(38%)	31(72%)	12(28%)	
Special impairment	nail	41(29%)	27(66%)	14(34%)	0.046
	inverted	9(6%)	5(56%)	4(44%)	
	face	14(10%)	11(79%)	3(21%)	
	scalp	52(37%)	34(65%)	18(35%)	
	genital	7(5%)	2(71%)	5(29%)	
	palms and soles	19(13%)	10(53%)	9(47%)	
Comorbidities	infections	13(8%)	9(69%)	4(4%)	0.049
	cardiovascular	53(31%)	29(55%)	24(45%)	
	metabolic	53(31%)	29(55%)	24(45%)	
	pneumology	10(6%)	5(50%)	5(50%)	
	neurology	9(5%)	4(44%)	5(56%)	
	atopy	4(2%)	3(75%)	1(25%)	
	gastroenterology	17(10%)	11(65%)	6(35%)	
	psychiatric	9(6%)	5(60%)	4(40%)	
Therapeutic switch	no previous biological therapies	67(59%)	44(61%)	23(56%)	0.00097
	1 switch	35(31%)	22(31%)	13(32%)	
	2 switches	11(10%)	6(8%)	5(12%)	
Biological agent	anti TNF- α	62(56%)	41(66%)	21(34%)	0.000054
	anti - IL	48(44%)	27(56%)	21(44%)	

Regarding those with a previous therapeutic switch, most of them had the PASI score at the initiation of the current biological therapy between '21-30' (n = 15), and those with 2 previous biological therapies totaled 5 people in this interval. In those without previous biological therapies, the '21-30' interval had the highest proportion with 36 patients (p = 0.46 - insignificant). Actual PASI score in those

with a single switch, at most - 49% (n = 17) '<2', two switches - 46% (n = 5) '<2' and without previous biological therapies most 48% (n = 32) had interval '2-10'. Although there were many therapeutic switches, it was still correlated with good disease activity. We evaluated the survival of drugs in second-line biologic therapies and estimated the risk of recurrent discontinuation due to adverse events or inefficiency in patients with psoriasis who failed a first biologic therapy Cause of discontinuation of previous biologic therapy, patients with a single switch: 4 cases with adverse reactions and 41 cases based on inefficiency, and for those with 2 previous biological therapies: 1 case of adverse reaction and 10 cases of therapeutic inefficiency. There are 31 patients with arthropathic psoriasis -15 women and 16 men, most of them (75%) being in the age range '> 40'. All patients in this category also associate nail touch.

As a number of hospitalizations, of those with a single biological therapy so far, 51% of patients (n = 34) required <5 hospitalizations throughout the study period, 25% (n = 17) between 5-10 hospitalizations, 12% (n = 8) needed more than 20 hospitalizations, 6% (n = 4) between 11-15, 6% (n = 4) between 16-20 hospitalizations. Of those with a therapeutic switch, 29% (n = 10) needed more than 20 hospitalizations, 23% (n = 8) between 16-20 hospitalizations, 20% (n = 7) between 5-10, 20% (n = 7) with less than 5 hospitalizations and 8% (n = 3) with hospitalizations between 11-15. Of those with 2 therapeutic switches, 37% (n = 4) are those with more than 20 hospitalizations, 27% (n = 3) between 16-20 hospitalizations and 18% (n = 2) between 11-15 and 18% (n = 2) between 5-10 hospitalizations.

DISCUSSION

The emergence of biological agents in the last two decades has dramatically improved the treatment of psoriasis and psoriatic arthritis (10). Although approved biological agents differ from country to country, biological agents commonly used for the treatment of psoriasis are classified into three groups: TNF - alpha inhibitors, IL -23 inhibitors and IL-17. However, the fact that there are so many options available has also caused confusion (11). The simpler idea that more of the available older biological agents are outdated may not be true. In practice, the variations of the clinical challenges faced by the clinician are vast. Given this, a biological agent considered to be obsolete may prove to be the best agent for a particular patient. For example, some experts now believe that etanercept, which was approved in 2004, is no longer worth considering because of its limited effectiveness. However, it is good to remember that etanercept has one of the best 'geriatric claims' of the FDA attesting to its safety in elderly patients, stating in essence that the risk for elderly patients is almost the same as the risk for younger patients (12). Other biological agents report opposition (i.e., older patients are at higher risk than younger patients, such as adalimumab) or do not have geriatric statements due to a lack of data in this population (12, 13). Another example is certolizumab, which is also an older agent. This agent can be easily forgotten with the assumption that it probably does not have a better effectiveness than other older biological agents for psoriasis. In reality, the PASI 75 achievement rate of certolizumab is close to that of newer IL-17 agents. Moreover, being an anti-TNF drug, its effectiveness for psoriatic arthritis is one of the best, given its high

performance for the treatment of psoriatic arthritis, which may not match the latest IL-23 agents. The authors' recommendation is therefore not to abandon the currently available biological agents, based on superficial assessments (13, 14).

Ellis *et al.* evaluated two network meta-analyzes that evaluated systemic therapies for moderate to severe psoriasis (15). They concluded that newer biological agents targeting the IL-12/23 and IL-17 axes appear to be more effective than older biological agents and oral agents. Sawyer *et al.* analyzed 17 studies that reported results at 40-64 weeks to evaluate long-term efficacy (16). Four 52-week randomized controlled trials showed that brodalumab was significantly more effective than secukinumab, ustekinumab and etanercept. Secukinumab was also more effective than ustekinumab and both exceeded etanercept. Evidence from 13 additional studies and four additional therapies (adalimumab, apremilast, infliximab and ixekizumab) showed that brodalumab was most effective, followed by ixekizumab and secukinumab, followed by ustekinumab, infliximab and adalimumab. Etanercept had the lowest long-term efficacy. They concluded that brodalumab is associated with a higher probability of a sustained PASI response, including complete clearance, at week 52 than the comparators (17, 18).

Sbidian *et al.* according to the meta-analysis of 140 reported studies (17), in terms of the percentage of patients who achieved PASI 90, infliximab, ixekizumab, secukinumab, bimekizumab, brodalumab, risankizumab and guselkumab were more effective than ustekinumab, adalimumab, certolizumab and etanercept. Furthermore, adalimumab and ustekinumab were more effective than certolizumab and etanercept. No significant differences were observed between any of the interventions and placebo for the risk of severe adverse events. In general, we can expect a rapid onset of efficacy on IL-17 inhibitors, especially brodalumab and ixekizumab (17). IL-17 inhibitors and IL-23 inhibitors, especially brodalumab, ixekizumab and risankizumab, have shown high long-term efficacy (18, 19, 20).

These biologics are able to produce a long-term remission of psoriasis, however, the disease usually recurs after stopping treatment. Drug survival is the time to discontinuation of the drug and is considered to be an important measure of real-world biological success of treatment (21, 22, 23). Biologicals with prolonged drug survival rates are associated with superior efficacy and safety profiles (24, 25, 26). In addition, prolonged adherence to treatment is noted as a surrogate measure for the success of treatment (26, 27).

CONCLUSIONS

However, because psoriasis is a chronic disease and some patients have to receive biologics for a long time, it could affect their long-term efficacy and safety. A longer observation is needed to clarify this. With the introduction of new biological substances and the discontinuation of others, an update of biological substances in psoriasis is delayed. Biological therapies have limits in terms of their performance. Perhaps the issue of the therapeutic switch and its timing should be reviewed. Understanding the benefits, risks and monitoring of patients with biological substances is becoming increasingly important for dermatologists. Although recent scientific advances have led to highly effective treatments for moderate to severe psoriasis, lower efficacy of biological treatments has been reported in those with

previous biological exposure and /or failure. Knowing the factors that predict the persistence or discontinuation of biological treatment is also important to understand the interaction between biological and certain cohorts of psoriasis patients.

CONFLICT OF INTERESTS AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

NEWS

REGENERATING THE CORNEAL NERVES WITH AN INNOVATIVE TREATMENT

In this prospective, interventional, before-and-after case series an evaluation is made regarding the efficacy of recombinant human Nerve Growth Factor (rhNGF) eyedrops for the regeneration of structure and function of the corneal nerves in a cohort of patients with neurotrophic keratopathy (NK) (N=18). All patients were evaluated at baseline, 4 and 8 weeks of treatment, and underwent a clinical assessment of corneal sensitivity, regeneration, and in vivo corneal nerve morphologic examination. The authors suggest that topical treatment with rhNGF increases sub-basal nerve density and corneal sensitivity thus promoting healing of corneal ulcers and persistent epithelial defects in patients with NK. (Mastropasqua L *et al*. In vivo evaluation of corneal nerves and epithelial healing after treatment with recombinant nerve growth factor for neurotrophic keratopathy. *Am J Ophthalmol* 2020; 217: 278-86).

IMMUNE DEFICIENCY AND INFECTION IN PEDIATRIC CHRONIC RESPIRATORY PATHOLOGY

IMMUNE DEFICIENCY AND INFECTION IN PEDIATRIC CHRONIC RESPIRATORY PATHOLOGY (Abstract). The relationship between infection and the immune system is certain, and the infection has a negative impact on the functionality of the respiratory system in children with chronic pathology. **Material and methods**: The study group consisted of 107 children with chronic respiratory pathology, diagnosed and followed in the IInd Pediatric Clinic of the "Sf. Maria" Emergency Clinical Hospital for Children Iasi Romania with asthma or cystic fibrosis, subsequently associated with immune deficiency or hyper IgE. **Results**: 94 patients were diagnosed with asthma and 13 with cystic fibrosis. Most hospitalizations are noted in children aged 3-10 years (61.68). 79 cases associated pathologies that can be considered as factors favoring recurrent infections in children with chronic respiratory distress. 70 patients had IgA deficiency. Of these, 30 children (42.86%) had selective Ig A deficiency, 31 (44.29%) Ig G deficiency, 6 (8.57%) hyper Ig E, and 3 (4, 29%) also associated class M immunoglobulin deficiency. 14 cases (13.08%) had chronic bacterial airway colonization, and 8 children (57.14%) had a chronic lung infection with *Pseudomonas aeruginosa*, 3 children (21.43%) were colonized with *Staphylococcus aureus*, 2 patients (14.29%) with *Haemophillus influenzae*. **Conclusions**: Maintaining an optimal immune status in children with asthma or cystic fibrosis can lead to a slower progression of both conditions, delay the deterioration of respiratory function status, and increase the quality of life associated with harmonious mental and physical development. **Keywords**: CYSTIC FIBROSIS, CHRONIC RESPIRATORY DISTRESS, IMMUNE DEFICIENCY.

Studies in the literature indicate that there is a link between chronic respiratory disease, immune deficiency and associated infections, so we looked at the clinical, anamnestic, biological and paraclinical features of pediatric patients diagnosed with asthma or cystic fibrosis and associated with frequent respiratory infections. The relationship between infection and the immune system is certain, and the infection has a negative impact on the functionality of the respiratory system in children with chronic pathology. This forms a vicious circle consisting of the immune deficiency, chronic inflammation and airway remodeling, which accompany cystic fibrosis and asthma, and recurrent respiratory infections that amplify the existing inflammatory process.

MATERIAL AND METHODS

The study group included 107 children with chronic respiratory pathology, diagnosed and followed in the IInd Pediatric Clinic of the "Sf. Maria" Emergency Clinical Hospital for Children from Iasi. The inclusion criterion was represented by the positive diagnosis of asthma or cystic fibrosis, subsequently associated with immune deficiency or hyper IgE, observed by the values of immunoglobulins IgA, IgG and IgM, respectively IgE.

RESULTS

Of the 107 patients enrolled in the study, 66 (61.68%) were boys and 41 (38.32%) were girls. Therefore, an inhomogeneous distribution is observed in the studied group, with a predominance of males.

Of the 107 patients admitted to the study, 94 were diagnosed with asthma and 13 with cystic fibrosis; the tendency to affect the males was observed in both pathologies (fig. 1).

Most hospitalizations are noted in children aged between 3 and 10 years, respectively 66 patients (61.68%); in the age group 0-1 years, no patients were included, in the range between 1 and 3 years there were 17 patients (15.88%), and between 10 and 18 years there were 24 patients (22.44%) (fig. 2).

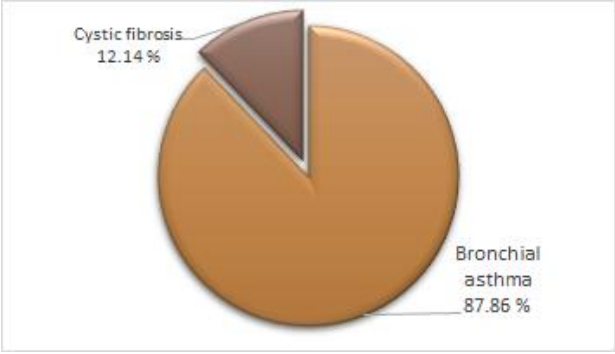

Fig. 1. Chronic pathologies distribution

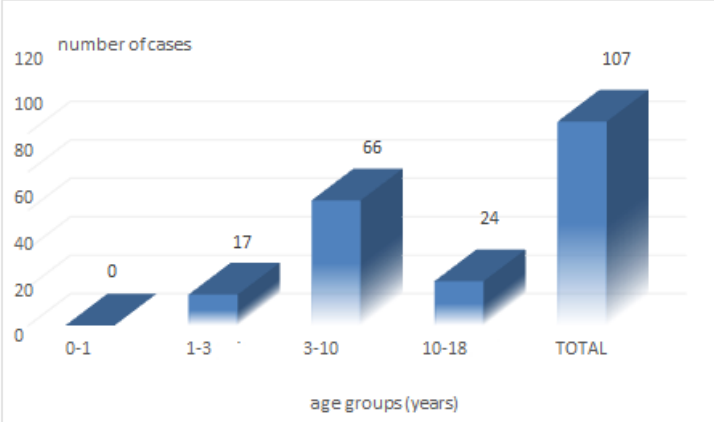

Fig. 2. Age distribution for patients with chronic respiratory pathology

At the time of presentation of the patients at the hospital, 68 (63.55%) of the patients were admitted showing signs and symptoms specific for respiratory infections. For clinical and biological evaluation, 34 (31.78%) patients presented with respiratory impairment, and 5 (4.67%) for gastrointestinal infections.

Pathologies associated with chronic respiratory damage

Out of a total of 107 patients, 79 of them had associated pathologies that can be considered as factors favoring recurrent infections in children with chronic respiratory distress.

In our study, of the 107 children analyzed, 28 (26.17%) did not associate other pathologies. Atopic manifestations were the most common associated pathologies, affecting 36 children (33.64%), and allergic rhinitis was diagnosed in most patients. Cardiovascular malformations followed in 11 patients (10.28%), obesity in 10 children (9.35%), as well as malnutrition, gastroesophageal reflux disease affected 6 children (5.61%) 5 children (4.67%) were associated with malabsorption syndrome, and one child (0.93%) was diagnosed with G6PD deficiency.

Immune deficiency

Following the results on the humoral immune system, out of a total of 107 children analyzed, a number of 70 patients (65.42%) had IgA deficiency. Of these, 30 children (42.86%) had selective Ig A deficiency, 31 (44.29%) also have Ig G deficiency, 6 (8.57%) had hyper Ig E, and 3 (4, 29%) also associated class M immunoglobulin deficiency.

Out of 13 children diagnosed with cystic fibrosis, 8 children (61.54%) had Ig A deficiency, and 5 children (38.46%) had Ig A concentration within normal limits. Of the 94 children diagnosed with asthma, 62 (65.96%) were found to have Ig A values below the normal limit, and 32 (34.04%) had values above 90 mg / dl.

Out of the group of 107 children studied, 57 (53.27%) had Ig G values lower than 800 mg / dl, and 50 children (46.73%) had normal values; 16 children (28.07%) had selective Ig G deficiency, 31 of patients (54.39%) also had Ig A deficiency, 8 children (14.04%) also had hyper Ig E, and 2 children (3.51%) also associated Ig M class deficiency. Of the 13 children diagnosed with cystic fibrosis, 9 of them (69.23%) had low Ig G levels, and 4 children (30.77%) had optimal immunoglobulin concentrations.

Immunoglobulins M represent approximately 8-10% of the total serum antibodies, with a concentration between 60-280 mg / dl. Of the 107 children examined, 11 (10.28%) had low Ig M concentrations, and in 96 children (89.72%) the Ig M concentration was within normal limits. In children with cystic fibrosis, there were 4 cases (30.77%) with Ig M deficiency, and 9 children (69.23%) had normal serum Ig M concentrations. Among the 94 patients diagnosed with asthma, 7 of them (7.45%) had Ig M deficiency, and 87 (92.55%) had a normal M immunoglobulin concentration.

Immunoglobulins E are the type of antibodies present in the lowest amounts in normal serum, constituting approximately 0.004% of the total serum antibodies. Out of a total of 107 patients analyzed, 32 of them (29.91%) had an increase in the concentration of Ig E, and 75 children

(70.09%) had an antibody concentration within normal limits. Among the 32 children with increased immunoglobulin E, 6 children had Ig A deficiency, 8 patients (54.39%) had Ig G deficiency, 2 children (14.04%) had decreased Ig M, and 16 children shows the selective increase of Ig E. Out of the 94 asthmatic children, 28 (29.79%) had elevated concentrations of immunoglobulins E, and 66 children (70.21%) had immunoglobulins E within normal limits; in the group of 13 children diagnosed with cystic fibrosis, 4 of them (30.77%) had a higher concentration of E immunoglobulins, and in 9 children (69.23%), the E immunoglobulins were within normal limits.

Chronic airway colonization

Of the 107 children studied, 14 of them (13.08%) had chronic bacterial airway colonization. In our study, 8 children (57.14%) had a chronic lung infection with *Pseudomonas aeruginosa*, 3 children (21.43%) were colonized with *Staphylococcus aureus*, 2 patients (14.29%) presented *Haemophillus influenzae* chronic infection and in only 1 child (7.14%) the presence of *Burkholderia cepacia* was highlighted (fig. 3).

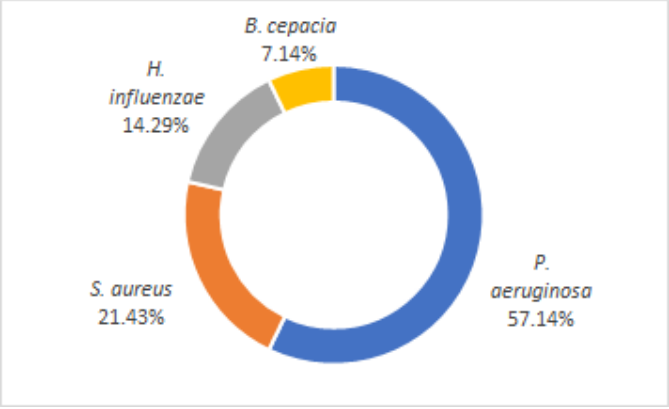

Fig 3. Chronic bacterial colonization in selected patients

DISCUSSION

A number of studies in the literature have shown that there is a higher prevalence of respiratory pathology in males compared to females, the male being also considered a risk factor in a large number of chronic respiratory diseases with childhood onset. Although they have higher lung volumes than girls, most boys have lower values of spirometry testing; other studies show that, with age, in male patients, the increase in airway resistance is much more pronounced than in females (1, 2).

Seemingly healthy male children have a higher Ig E concentration and a higher rate of positive skin tests than girls of the same age. These two hypotheses, in association with narrower airways and increased reactivity, place male children at a higher risk of developing asthma (3). A study conducted in 2013 at the Children's Hospital of Colorado showed that exacerbations caused by asthma were more common in boys than in girls, with values of 1:93 for females and

1:61 for males (4).

Cystic fibrosis, by decreasing the ciliary clearance and the interaction with the defense mechanisms of the respiratory tract, determines the difficult elimination of microorganisms, thus favoring the appearance of infections. Asthmatic children have a four times higher risk of developing pneumococcal diseases, the infections being all the more frequent as the asthma is less controlled, and the corticosteroid administration is in high doses (5, 6).

In our study, 79 of them had associated pathologies that can be considered as factors favoring recurrent infections in children with chronic respiratory distress. Atopic diseases are the most common pathology associated with asthma, and in the case of cystic fibrosis, malabsorption, malnutrition and damage to the cardiovascular system. Allergic rhinitis, atopic dermatitis and urticaria are among the group of atopic diseases, along with allergic asthma. Asthma has been observed more frequently in children who associate with obesity and are much more difficult to control. Studies in the literature state that approximately 40% of children with allergic rhinitis have or will develop asthma. Most often, rhinitis is also associated with allergic conjunctivitis, and atopic eczema frequently precedes the onset of allergic rhinitis (7).

More than 85% of children diagnosed with cystic fibrosis were also associated with protein or fat malabsorption syndromes, which, over time, caused malnutrition. The latter is associated with an acquired immunodeficiency syndrome, decreased secretory Ig A, as well as a degradation of the nonspecific local defense system, such as loss of mucosal integrity and lymphokine overproduction (8).

In children with Ig A deficiency, along with recurrent respiratory infections, autoimmune and atopic disorders often have a much higher incidence compared to those who do not have this immune system impairment. Studies to date have shown that asthma is much more common and has more severe symptoms in children with immunoglobulin A class deficiency. IgA inhibits the attachment of allergens in the environment, which causes the development of asthma. (4, 6).

Chronic airway colonization is a common problem in asthmatic or cystic fibrosis patients, although there is a higher prevalence among children with cystic fibrosis.

A study of a group of 42 patients with cystic fibrosis found isolates of *Candida spp*, and in over 70% of cases, the isolates were positive for *Aspergillus terreus* identified as the most common species of *Aspergillus*, followed by *A. fumigatus*. Bacterial and fungal co-colonization was found in 16.6% of patients and more than half of the samples were positive for *Aspergillus* and *Candida* (9).

Widespread use of immunosuppressive drugs has broadened the spectrum and increased the incidence of human diseases due to common arthroconidia fungi in the environment and ascomycetes that occasionally lead to opportunistic infections in people. A child with cystic fibrosis with pulmonary exacerbation and *Arthrographis kalrae* isolated from bronchoalveolar lavage fluid has been reported (10).

In a study conducted in the AREST CF cohort conducted in Australia, the authors found that children with CF have pulmonary infiltration of CD66b, and granulocytes and elevated levels of MIP-1α, MIG, MCP-1, IL-8 and IL-6. Inflammatory cells

collected by bronchial lavage expressed higher levels of activation and migration markers compared to systemic markers (11).

CONCLUSIONS

Therefore, immune dysfunction is a very important risk factor among these patients, contributing substantially to the morbidity and mortality associated with the underlying pathologies. Studies to date support the significant contribution of immune deficiency in chronic pathologies. In the case of cystic fibrosis, the immune deficiency can have multiple causes: damage to the components of the immune system by mutation or an innate defect, but most often occurs secondary to malnutrition or inflammatory status caused by chronic lung infection. Paradoxically, in this group of patients, the fight of the immune system against chronic lung infection contributes substantially to the progression of lung disease. In asthmatic patients, respiratory infections, common in normal children, can be particularly serious; they also have a significant negative impact on the quality of life and especially on the pathologies they can develop as adults (chronic obstructive pulmonary disease, which is known to be a debilitating condition, associated with multiple pathological implications and huge costs).

In conclusion, focusing on maintaining an optimal immune status among children with asthma or cystic fibrosis can lead to a slower progression of both conditions, delay the deterioration of respiratory function status, and increase the quality of life associated with harmonious mental and physical development.

CONFLICT OF INTEREST AND FUNDING

The author declares that there is no conflict of interest, and she received no specific funding regarding this scientific research.

REDUCTION/ELIMINATION OF BLOOD EOSINOPHILS IN SEVERE ASTHMA: SHOULD THERE BE A SAFETY CONSIDERATION?

Eosinophils play a central role in the inflammation of asthma and are the target of new biologic treatments for patients with severe asthma. Biologics targeting the IL-5 pathway have been shown to reduce asthma exacerbations, improve lung function, reduce oral corticosteroid use, and improve quality of life, accompanied by reduced or even eliminated blood eosinophils. Eosinophils have been associated with host protection and tumor growth, raising potential concerns about the consequences of these long-term therapies that reduce or eliminate them. Areas covered In this review, we explore the current safety profile of biologics regarding the impact they may have on blood eosinophils, trying to answer the question about any safety consideration. There is no doubt that the emergence of specific biologic therapy represents a revolution in severe asthma treatment as the clinical benefit has been clarified through large randomized controlled trials and real-life studies as well. Furthermore, targeting eosinophils through biologic compounds of the IL-5 pathway has shown impressive clinical results irrespective of reduction or elimination of blood eosinophils. However, is it safe to minimize a naturally existing cell? Theoretically speaking no, but practically the answer seems to be yes. Omalizumab, although not a specific antieosinophilic compound has proved to be safe after more than 15 years of use in everyday clinical practice with no safety reports regarding eosinophils. Mepolizumab has already gained a more than 5 years' experience and Reslizumab and Benralizumab have data of up to 3 years exposure with acceptable safety regardless of the degree of blood eosinophils decrease or elimination. Two plausible explanations seem to prevail. First, reduction or elimination of blood eosinophils does not mean vanishing eosinophils from the whole body as they are still present in other sites such as tissue airways or bone marrow. Second, as different types of eosinophils may exist, in different kind of condition such as steady state or inflammatory, it is not clear, yet which type of eosinophils is the real target of the IL-5 pathway biologics. If eosinophilic inflammation still constitutes a treatable trait for severe asthma in the future, it is likely to phenotype eosinophils along with the patients. Despite the different impact of the several biologics on eosinophils depletion, existing evidence does not support an increased infection risk, whereas the risk to benefit ratio, favors the use of IL-5 pathway biologics for severe asthma. Although long term studies are needed, the published evidence up to now supports a convincing anti-eosinophil and anti-IL-5 pathway blockade safety profile (KonKatsoulis K, Kipourou M, Loukides S. Reduction/elimination of blood eosinophils in severe asthma: should there be a safety consideration?, *Expert opinion on biological therapy* 2022; 22(3): 377-384 / doi.org/10.1080/14712598.2021.1960977).

SYSTEMIC COMPLICATIONS OF CHRONIC ALCOHOL CONSUMPTION. CASE-CONTROL STUDY CORPSES *VERSUS* SURVIVING PATIENTS

SYSTEMIC COMPLICATIONS OF CHRONIC ALCOHOL CONSUMPTION. CASE-CONTROL STUDY CORPSES *VERSUS* SURVIVING PATIENTS (Abstract) **Objective:** The aim of this prospective study is to investigate the forensic cases of the Institute of Legal Medicine (ILM) Iasi compared to a group of living patients, based on chronic alcohol consumption in the past. **Material and methods:** The study group consisted of 120 subjects, of which 60 cadavers from ILM Iasi, alleged victims of chronic ethanol consumption, and 60 patients admitted to the Cardiology Clinic I of the "Sf. Spiridon" County Clinical Emergency Hospital from Iasi, in order to perform a case-control study. **Results**: The studied cases are dominated by male patients over 60 years of age, from rural areas. A cut off value of ethyl glucuronide (EtG) greater than 500 ng/ml proves to be a good predictor in the determinism of liver cirrhosis and dilated cardiomyopathy. **Conclusions**: Elevated levels of EtG have been shown to be a good predictor of liver cirrhosis and dilated cardiomyopathy. **Keywords:** CHRONIC ALCHOOL CONSUMPTION, LIVER, CARDIOVASCULAR, DISEASE.

In forensic medicine, a number of methods are used to determine markers of chronic ethanol consumption in biological products taken from corpses. Alcohol abuse, due to the medical consequences it generates, is an important public health problem (1-3). Studying the protocols in identifying markers of chronic alcohol consumption, in laboratories in Romania and other countries, has shown that alcohol directly affects the most important organs and tissues, leading to systemic dysfunctions, which can have severe health consequences, ranging from decreased quality of life to death (2, 4-7). Chronic alcohol users may experience significant functional and morphological changes (8-13). Overall, all tissues and organs are vulnerable to alcohol

abuse, but almost all medical consequences are only partially reversible with abstinence (14-19).

MATERIAL AND METHODS

The study group consisted of chronic alcohol consumers, divided into two groups, as follows:

- Group I - 60 chronic alcohol consumers, deceased at home; corpses examined in the Institute of Legal Medicine (ILM) Iasi;

- Group II - 60 patients hospitalized in the Cardiology Clinic I of the "Sf. Spiridon" County Clinical Emergency Hospital Iasi.

The present prospective research was conducted between April and August 2021. It was performed with the approvals of the Ethical Commission of "Grigore T. Popa" University of Medicine and Pharmacy, Iasi (Notification no. 9421 / 12th June 2020) and the Ethical Commission of "Sf. Spiridon" County Clinical Emergency Hospital from Iasi (Notification no. 29 / 8th April 2021). A written informed consent from each patient was obtained and enrolment in the research was voluntary. All steps were taken to protect the privacy of the research subjects (patients and corpses) and the confidentiality of their personal information.

In order to highlight the systemic organ changes, tissues taken from the liver, stomach, colon, small intestine, pancreas and heart were microscopically analyzed. Biological samples were taken from the studied cases, at a maximum of 4 hours after death, to determine the level of ethylglucuronide (EtG) by gas-chromatographic method.

The liver tissue samples taken were immunohistochemically analyzed.

In living patients, clinical and laboratory data related to chronic alcohol consumption were selected from the medical records, and the level of EtG in blood or urine samples was determined by the gas-chromatographic method.

The data were centralized in an *SPSS 18.0* database and processed with the statistical functions for which they are suitable, at the significance threshold of 95%.

The ANOVA test was used to calculate descriptive statistical indicators: minimum, maximum, average, median, standard deviation, standard error of the mean, variance.

The Skewness test ($-2 < p < 2$) validates the normality of the series of values.

In calculating the significant difference between the two means, the t-Student test considers the measurement of variability and the weight of observations for the series of values with normal distributions.

Chi square is a nonparametric test that compares 2 or more frequency distributions from the same population; it is applied when expected events are excluded.

RESULTS

Both study groups were dominated by patients over 60 years of age (53.3% *vs.*. 66.7%; p=0.135); male sex (76.7% *vs.*. 83.3%; p=0.360); coming from rural areas (51.7% *vs.*. 66.7%; p=0.094) (tab. I).

By plotting the receiver operating characteristic (ROC) curve, it is proved that age (AUC=0.649; CI 95%: 0.543-0.754) and the environment of origin (AUC=0.603; CI 95%: 0.496-0.711) are good predictors in the determinism of lethality (tab. II, fig. 1).

TABLE I

Comparative demographic data by study group

Demographic characteristics	Group I (n=60)	Group II (n=60)	Statistical test	p
Average age ± SD, years (min-max)	59.52 ± 14.39 (18-81)	64.97 ± 9.42 (43-82)	t-Student test	0.056
≥ 60 years, n(%) < 60 years, n(%)	32 (53.3%) 28 (46.7%)	40 (66.7%) 20 (33.3%)	Chi^2 test	0.135

Sex	0.468	0.056	0.576	0.358-0.578
Environment	0.603	0.055	0.060	0.496-0.711

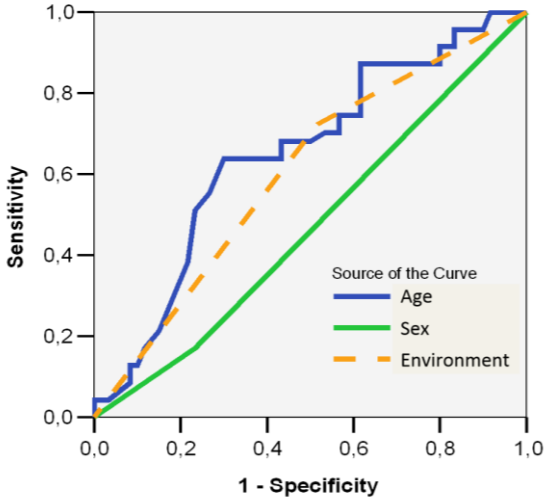

Fig. 1. ROC curve. Demographic data - predictors of death

Digestive complications

In patients who died, excessive accumulation of fat inside the liver cells was highlighted microscopically, which hinders the functioning of the liver (fig. 2).

Also, in the microscopically studied cases, an inflammation of the liver was identified, accompanied by damage of the liver cells (fig. 3).

Alcoholic cirrhosis is the most severe complication of alcoholic liver disease (ALD) (20, 21). In cirrhosis, normal liver cells are replaced by dysfunctional fibrous cells (fig. 4).

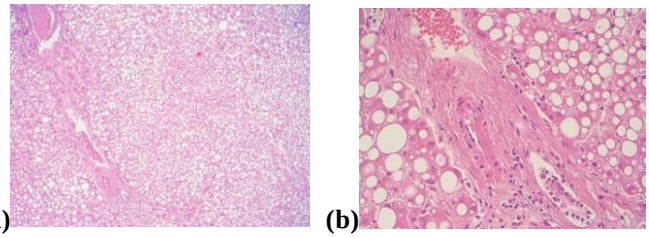

Fig. 2. Steatotic liver (ILM Iasi collection). **(a)** liver with lesions of diffuse micro- and macrovesicular steatosis, HE stain, magnification 10x; **(b)** hepatocytes with micro- and macrovesicular steatosis, reduced mononuclear inflammatory infiltrate in the portobiliary space, HE stain, magnification 40x

Starting from the classical histopathological study (22, 23), it was necessary to continue it with immunohistochemical methods. The following ***immunohistochemical changes*** (IHC) in cirrhosis were found in the study (figs. 5-7):

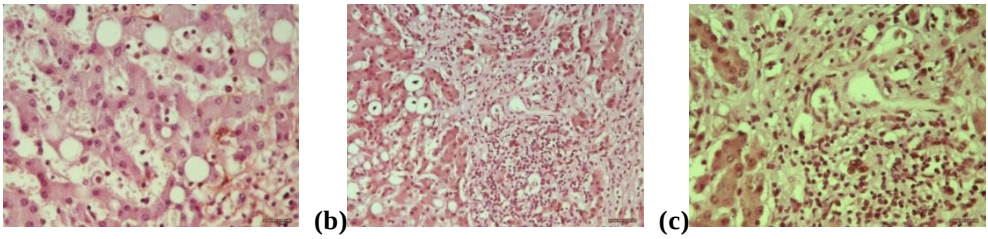

Fig. 5. IHC changes in cirrhosis (ILM Iasi collection). **(a)** 289-2 Ki67, x400. Ki has values below 1% **(b)** 289-2 p53, x200. p 53 it is intensely positive in 10% of the nuclei of bile duct canaliculi and only in 4% of the liver cell nuclei; **(c)** 289-2 p53 x400. Similar image, but with a larger magnification

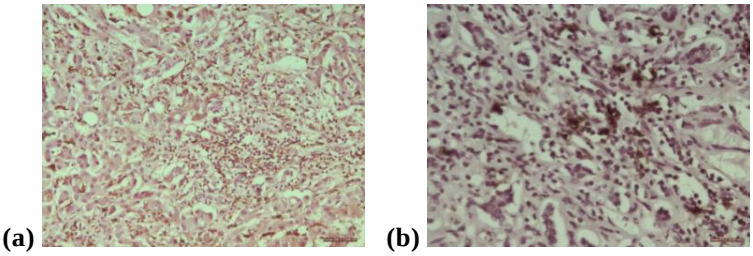

Fig. 6. IHC changes in cirrhosis (ILM Iasi collection). **(a)** 289-2 CD68, x200. CD68 is intensely positive in the macrophages in the inflammatory infiltrate in the portal spaces and in the Kupfer cells in the remaining liver parenchyma; **(b)** 372-2 CD20, x400. CD20 is intensely positive in the rare B lymphocytes in the inflammatory infiltrate in portal spaces

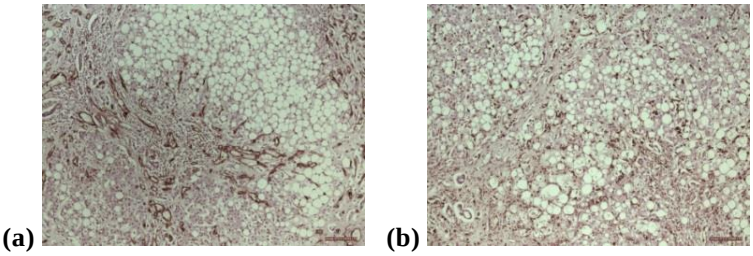

Fig. 7. IHC changes in cirrhosis (ILM Iasi collection). **(a)** 372-2, CD34, x100. CD34 is intensely positive in the endothelial cells of the numerous newly formed capillaries in the greatly enlarged portal spaces; **(b)** 372-2, CD68, x100. CD68 is intensely positive in the macrophages in the inflammatory infiltrate in the portal spaces and in the Kupfer cells in the remaining liver parenchyma

Exposure of the gastric mucosa to ethanol causes pathological changes (fig. 8), such as the inflammatory process, hemorrhagic erosions, and even acute ulcers. Lesions of the gastric mucosa, accompanied by a significant decrease in gastric blood flow and increased reactive oxygen species, imply a role of xanthine oxidase in ethanol-induced gastric hemorrhagic erosions (20).

Alcohol consumption is the main cause of the development of chronic pancreatitis and the second etiology of acute pancreatitis. The mortality of acute pancreatitis depends on its necrotic hemorrhagic character and the initial inflammatory response, while pain, malnutrition and diabetes are the main problems in the management of chronic pancreatitis. From the ILM case series, a histological presentation of a necrotic-hemorrhagic pancreatitis lesion was chosen as an example (fig. 9).

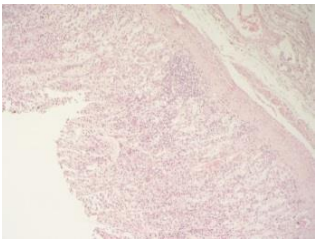

Fig. 8. Gastric mucosa greatly thickened by the presence of an abundant mononuclear inflammatory infiltrate, HE stain, magnification 10x, (ILM Iasi collection)

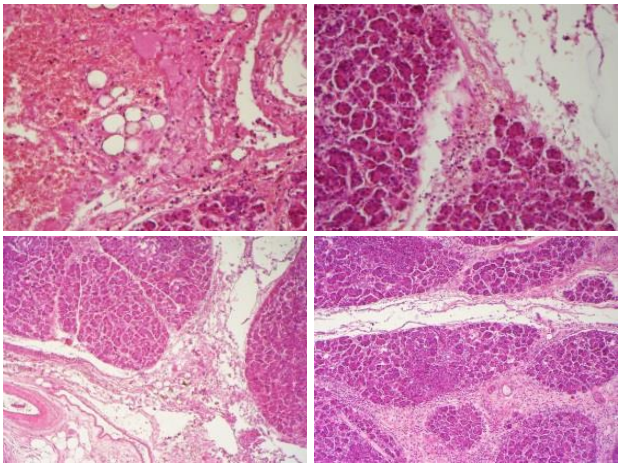

Fig. 9. Microscopic images for necrotic-hemorrhagic pancreatitis, HE stain, magnification 40x, (ILM Iasi collection)

In the studied case series, a significantly higher average level of EtG was found in the corpses in which it has been identified hepatic steatosis (3244 *vs.* 484 ng/ml; p=0.012), alcoholic hepatitis (4,179 *vs.* 520 ng/ml; p=0.001), liver cirrhosis (1,184 *vs.* 817 ng/ml; p=0.05), and chronic gastritis (1063 *vs.* 461 ng / ml; p = 0.049), compared to the level recorded in the living patients (tab. III).

By plotting the ROC curve, a cut off value of EtG of 514 ng/ml proves to be a good predictor in the determinism of liver cirrhosis (AUC=0.635), with a sensitivity of 64.3% and a specificity of 68.9% (tab. IV, fig. 10).

TABLE III

Average level of EtG related to the gastrointestinal complications

Complication type	Group I	Group II	t-Student test
Hepatic steatosis	3418 ± 2103	332 ± 161	**0.004**
Alcoholic hepatitis	6118 ± 3890	328 ± 109	**0.001**

Cardiovascular complications

The cardiac response to alcohol reflects the individual's physiology, rate of consumption, and amount of alcohol ingested. The observed postmortem histological changes in the ILM subjects are detailed in

the followings (fig. 11).

Histological evidence of myocardial injury with myocyte death is observed in the intramyocardial fibrous tissue (fig. 12).

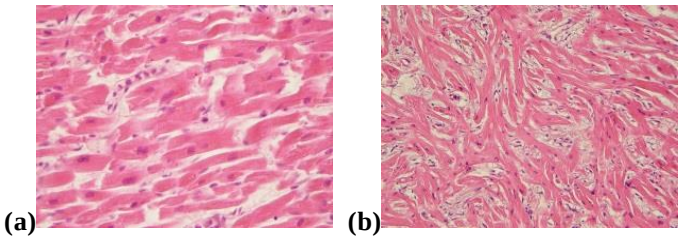

Fig. 11. Dilated cardiomyopathy (ILM Iasi collection). **(a)** myocardial fibers with a wavy, ischemic appearance, HE stain, magnification 40x; **(b)** heart with myocardial fibers with disorganized architecture, separated by fibrous tissue, HE stain, magnification 40x

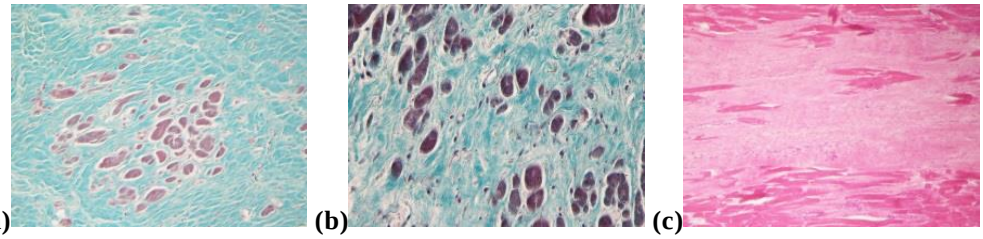

Fig. 12. Myocardial fibrosis (ILM Iasi collection). **(a)** heart with cytological architecture modified by the presence of abundant fibrous tissue, highlighted by green staining, and atrophic myocardial fibers, Masson's trichrome stain, magnification 30x; **(b)** abundant intramyocardial fibrous tissue highlighted by green staining, atrophic myocardial fibers, Masson's trichrome stain, magnification 40x; **(c)** heart with large areas of fibrosis, HE stain, magnification 30x

From the LMI cases it has been selected images of the heart with areas of recent acute myocardial infarction (fig. 13).

In the studied groups, a significantly higher average level of EtG was found in the corpses with chronic heart failure (3361 *vs.* 341 ng/ml; p=0.001) and dilated cardiomyopathy (1178 *vs.* 403 ng/ml; p=0.012), compared to the level recorded in living patients (tab. V).

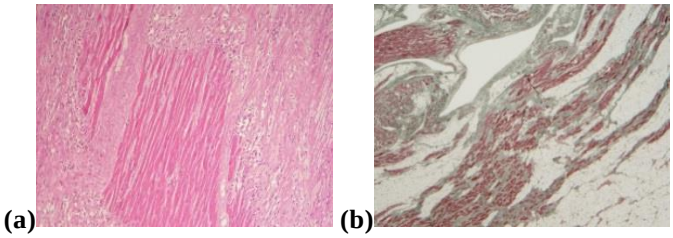

Fig. 13. Acute myocardial infarction (ILM Iasi collection). **(a)** heart with areas of recent acute myocardial infarction, anucleate myocardial fibers, eosinophils, HE stain, magnification 20x; **(b)** heart with cytoarchitecture modified by the presence of abundant fibrous and adipose tissue, atrophic myocardial fibers, Masson's trichrome stain, magnification 20x

TABLE V

Average level of EtG related to the cardiovascular complications

Complication type	Group I	Group II	t-Student test
Dilated cardiomyopathy	1178 ± 372	403 ± 372	**0.012**
Chronic heart failure	3361 ± 1593	342 ± 381	**0.001**
Acute myocardial infarction	462 ± 310	313 ± 266	0.474

By plotting the ROC curve, a cut off value of EtG greater than 500 ng/ml proves to be a good predictor in the determinism of dilated cardiomyopathy (AUC=0.655; CI95%: 0.540-0.770; p=0.026), with a sensitivity of 66% and a specificity of 60% (tab. VI, fig. 14).

TABLE VI

DISCUSSION

Alcohol is a major risk factor for many chronic diseases and one of the leading causes of "predictable" morbidity and mortality worldwide. It is estimated that alcohol triggers 2.5-3.3 million deaths in the world each year, accounting for almost 6% of all global deaths (24-26).

A World Health Organization (WHO) report on the relationship between alcohol and health has shown that alcohol abuse is responsible for at least 60 major types of acute or chronic diseases.

The progression of the alcoholic liver disease (ALD) is complex and depends not only on the amount and pace of alcohol consumption, but also on a variety of genetic and environmental factors. In general, men who ingest more than 100 g of ethanol every day, for more than 5 years, are at the highest risk of developing alcoholic hepatitis; however, women may also develop alcoholic hepatitis after ingesting small amounts of ethanol for shorter periods of time (11, 27).

Some studies estimate that about two billion people worldwide are consuming alcoholic beverages in excess (12).

The liver cell translates alcohol consumption as a "preferred fuel". Regardless of whether the consumption of alcohol, in quantity, is reduced or increased, it disrupts gluconeogenesis and leads to the shunting of the metabolic transformation of certain amounts of carbohydrates into fats. In the presence of constant levels of alcohol in the blood (80 mg/dl), liver damage begins with steatotic transformation of the liver, followed by alcoholic hepatitis and perivenular fibrosis, and in the last phase leading to liver cirrhosis (28).

Depending on the frequency of the number of cases, the present study focused on three major liver diseases with thanatogenerative potential: hepatic steatosis (15), alcoholic hepatitis (16, 29-31) and liver cirrhosis (32).

Up to 35% of heavy alcohol users develop chronic, moderate or severe hepatitis. The damage is reversible over time if alcohol intake is stopped. In the severe, acute form, the disease can set in suddenly, after ingesting a large amount of alcohol in a short time and can cause immediate complications leading to death (6).

Between 10 and 20% of heavy drinkers develop cirrhosis, usually after 10 or more years of consumption. Fibrosis is the first stage of scar tissue formation; however, when fibrosis accumulates and significantly occupies the organ, cirrhosis develops (33).

For a long time, hepatic steatosis has been considered a relatively harmless side effect of alcohol consumption, but recent studies have shown that people with alcohol-induced steatosis are vulnerable to developing alcoholic steatohepatitis, liver fibrosis, cirrhosis and even liver carcinoma (14, 15, 34, 35). However, hepatic steatosis is fully reversible if alcohol consumption is completely discontinued (36).

Alcoholic hepatitis is a chronic inflammatory disease, associated with high morbidity and mortality, in the context of chronic or excessive alcohol consumption (29). It causes chronic liver failure, jaundice, coagulation disorders, marked asthenia, ethanolic encephalopathy, etc. Several studies have shown that the prognosis of alcoholic hepatitis is poor if the patient continues to consume alcohol, with death occurring in 20-50% of cases, in approximately 28 days after the clinical onset of the disease (16, 30, 31). Chronic liver inflammation, associated with hepatocyte necrosis, disrupts local homeostasis, and induces a regenerative, anarchic process, characterized by the production of an extracellular matrix (ECM), and especially fibrillar collagen, with the onset of liver fibrosis. Liver fibrosis induced by excessive alcohol consumption is progressive and eventually leads to cirrhosis, which in turn, causes more than 1 million deaths

worldwide each year (37). Moreover, liver cirrhosis can become complicated with ascites that would be refractory to diuretic medication in approximately 10% of patients (38). Often these patients have also renal pathology that progresses to end-stage renal disease (ESRD), necessitating renal replacement therapy. Multiple pathogenetic factors participate in refractory ascites and important morphological changes of the peritoneal membrane also occur in the patients with long term dialysis (39, 40).

The cellular and molecular mechanisms of ALD have become well known in recent years. In the first stage, alcohol induces hepatic steatosis due to the reduction of fatty acids, the activation of lipogenic enzymes, and the appearance of reactive oxygen species (ROS) and proinflammatory cytokines. All this leads to the onset of a local inflammatory process, where neutrophils are predominant. It has been suggested that the large number of neutrophils is triggered by the activation of hepatocyte proteases, and by the appearance and growth of ROS.

Proinflammatory cytokines such as tumor necrosis factor-alpha (TNF-α), interleukin-1 (IL-1), IL-6, and IL-8 are activated and secreted by Kupffer cells and other inflammatory cells (neutrophils, macrophages), which accumulated in Kiernan spaces, following chronic alcohol consumption (29). The presence of a local inflammatory process, even at a low level, can lead to liver fibrosis, a more severe stage of excessive alcohol consumption. Hepatic fibrosis is the result of qualitative and quantitative changes in the ECM. With its onset, the normal architecture of the liver is altered, leading to liver failure. Left untreated, fibrosis can progress to cirrhosis, followed most commonly by severe liver failure and death (32, 41, 42). The process of hepatic fibrillogenesis interferes with the cells present in the liver. Thus, hepatic stellate cells (Ito cells), under the influence of cytokines and chemokines, synthesized by inflammatory cells, undergo a trans differentiation into myofibroblasts. Proliferating myofibroblasts are one of the main sources of ECM molecular excess (type I and III collagen), as well as other proteins in the structure of pathological fibrous tissues (43-45). Kupffer cells are also involved in the process of liver fibrogenesis. They synthesize a multitude of powerful cytokines, through which they activate the liver stellate cells and transdifferentiate them into myofibroblasts (46).

Our study showed that in individuals with chronic or excessive alcohol consumption, there is intense Kupffer cell activity and trans differentiation of liver stellate cells into myofibroblasts.

Based on the chronic alcohol abuse cases analyzed in forensic pathology, pathological anatomy, and forensic toxicology laboratories, we obtained data proving that the amplitude of the histopathology changes in the heart are associated with a significantly higher level of EtG in the blood. Regarding myocardial lesions, we identified most of them in cases with dilated cardiomyopathy, and they were present in both myocytes and the myocardial intercellular conjunctival matrix. We believe that all myocardial injuries and changes are the result of alcohol abuse.

According to some studies, the cardiovascular system is the second most affected by the global toxicity of ethanol, after the liver and the gastrointestinal tract (47, 48). Alcohol abuse can cause systemic atherosclerosis (49), high blood pressure and

cardiac arrhythmias (50). Moreover, in a very high percentage, it leads to progressive damage of the myocardium, also known as "alcohol-dilated heart disease" (51-56).

Chronic alcohol consumption is one of the leading causes of dilated cardiomyopathy, characterized by dilated left ventricle and reduced systolic / diastolic function, which eventually progresses to congestive heart failure. Chronic exposure to alcohol can exacerbate heart failure of several etiologies due to volume overload. The cardiac response to alcohol reflects the individual's physiology and depends on the rate of consumption and the ingested amount. People with left ventricular dysfunction show predominantly the inhibiting effects of the alcohol, which leads to a decrease in ejection fraction (57). Our histopathology findings in the left ventricular myocardium of the subjects with dilated cardiomyopathy can also explain the macroscopic aspect of the heart at necropsy, and provide a morphological substrate for the clinical symptoms the patients complained of, before death.

Myocardial damage, in the case of alcohol abuse, is caused by both the alcohol and the resulting metabolites, especially acetaldehyde, which decrease the structural proteins and reduce the myocyte contractility (58, 59). The lesions produced in myocytes by alcohol are extremely diverse, targeting cell membrane, receptors, mitochondria, ribosomes, or cytoskeleton. This is happening because ethanol has a highly reactive molecule, which is small in size and has a high diffusion capacity (60, 61). Ethanol increases the permeability of the cell membrane, including intracellular organelles, disrupts the activity of ion channels (Ca^{2+}, Na^{+}/K^{+}) together with the cellular signaling mechanisms, and activates apoptosis (62, 63). Other studies have shown that alcohol disrupts the synthesis of ribosomal proteins, contributing to the depletion of non-contractile proteins in the sarcoplasm (61). The excessive consumption causes the mitochondria to enlarge, leading to the occurrence of megamitochondria, the degeneration of the inner membrane folds, and even the fragmentation of these folds (64). Moreover, the mitochondria will produce ROS that can have either adaptive or harmful effects. Elevated ROS levels can eventually lead to apoptosis by promoting the oxidation of lipids, proteins and deoxyribonucleic acid (DNA); a phenomenon that is described in alcoholic dilated cardiomyopathy (65-67).

Our study confirms the observations of other authors who claim that chronic alcohol abuse reduces the structural synthesis of proteins, with sarcomere disorganization, focal dissolution of myofibrils, cell vacuolation and myocytolysis (68). As illustrated above, many studies show that changes in the intercellular conjunctival matrix are present in almost all cases of dilated cardiomyopathy, caused by excessive alcohol consumption (69). The most obvious is myocardial fibrosis, which results from a process of tissue regeneration after the apoptosis or necrosis of myocytes. This myocardial regeneration is inefficient since the fibrosis process is being more extensive, leading to left ventricular dysfunction and heart failure (23, 70, 71).

As medical and endoscopic therapeutic procedures progress, surgical interventions have become increasingly rare, but still remain indispensable for some patients suffering of the complications of chronic alcohol abuse. Alcohol abuse, both alone and in connection with diabetes mellitus,

increases the risk for many cancers (72). Moreover, ethanol consumption by diabetes patients has worsening effect for the efficacy of antidiabetic drugs (73), so novel promising therapies are studied for treatment of diabetes and alcohol dependence involving nanodrug delivery systems (74, 75). Alcohol abstinence is important for patients who receive biologic medication for immune-mediated diseases (76) due to the interaction between alcohol and the proinflammatory cytokines.

The multidisciplinary approach towards patients who consume alcohol is the key to the success of care (8), and a modern approach of alcohol addiction should also consider the degree of satisfaction a patient has with his medication (77), during the abstinence period.

CONCLUSIONS

This prospective case-control study was performed on two groups of chronic alcohol users, 60 deceased patients that had their corpses examined in the Institute of Legal Medicine Iasi (Group I), and 60 living patients, hospitalized in the Cardiology Clinic I of the "Sf. Spiridon" County Clinical Emergency Hospital Iasi (Group II), which were monitored according to the established protocol, in order to highlight the risk factors that may cause lethality.

The dosage of ethylglucuronide (EtG) in blood or urine samples taken from corpses is the main marker for the diagnosis of chronic ethanol consumption, also endorsed by the investigation data and the necropsy diagnosis. All this information can lead to establish a certain diagnosis of chronic ethanol poisoning and help elucidate some inconclusive situations.

In the cases where corpses belonged to individuals suspected of chronic alcohol consumption that we analyzed in pathological anatomy and forensic toxicology laboratories, important histopathological changes of the vital organs were identified, which are correlated with a significantly increased level of EtG. Elevated levels of EtG are a good predictor of liver cirrhosis and dilated cardiomyopathy.

CONFLICT OF INTERESTS AND FUNDING

Authors declare that there is no conflict of interests, and they received no funding for this study.

NEWS

EFFICACY OF SUBCUTANEOUS CLOSED SUCTION DRAIN IN REDUCTION OF POSTOPERATIVE SURGICAL SITE INFECTION

Surgical site infections (SSIs) are the infections of wound after an invasive operative approach. It remains to be a major morbidity for patients undergoing surgeries although there have been tremendous improvements in the surgical techniques. Different interventions to suppress the selective serotonin reuptake inhibitors have been proposed. Many of them have been routinely used by surgeons like minimizing shaving, hand washing, and preoperative antibiotics and these are well accepted. Drains are used in major abdominal surgeries, hernia repairs, breast surgeries reducing collections in closed areas. Hematoma, serous fluid and dead space in surgical incision wounds raise the risk of infection as they serve as the platform for microbial growth. Studies have proved that the usage of subcutaneous drains has lowered the chances of infection. According to this study the comorbid patients, emergency cases and colorectal surgeries had a higher incidence of developing SSI. The most common organism isolated was *E. coli* followed by *S. aureus*. The assessment of these variables therefore helps in providing a prophylactic treatment to reduce the mortality in the high-risk patients. (Harish R, Kazi FN, Sharma J. Efficacy of Subcutaneous Closed Suction Drain in Reduction of Postoperative Surgical Site Infection. *Surgery Journal (New York, N.Y.)*, 2021; 7(4): e275-e280).

MEANING IN LIFE: CONFESSIONS OF SUICIDAL PATIENTS AND THE NEED FOR A LOGOTHERAPY-BASED NURSING

MEANING IN LIFE: CONFESSIONS OF SUICIDAL PATIENTS AND THE NEED FOR A LOGOTHERAPY-BASED NURSING (Abstract): A strong meaning in life (MiL) was described as a protective factor against the suicide. **Material and methods:** Accordingly, in this study we conducted a series of interviews with 31 hospitalized suicidal patients (mean age of 55 ±13.5) and 31 control patients (mean age of 58.7 ± 9.7) to evaluate their current MiL and potential means to recover it. The hospitalized patients have been known to the investigator for an average of 4.8 years (median 2.9 years). **Results:** Psychiatric patients have been deeply affected by the ruined family relationships and harmful psychosocial experiences marked by betrayals, deceptions, abuse, threats, insults, contempt, deceit etc. Accordingly, 71% (CI: 0.137-0.432) of suicidal patients and 19 % (CI: 0.637-0.908) of control patients have lost their MiL. Prayer and living their faith in God would represent motivational values to reach a MiL or constitute a MiL by themselves for 84 % (CI: 0.674-0.929) of the patients. It was also observed that the willingness to help other sufferers, the high need to love and to be loved, and to mean something to family and society represented a shared feature of suicidal patients and valuable sources for their MiL. **Conclusions:** a program of supportive logotherapy of suicidal patients and their inclusion in activities of helping other sufferers would represent a beneficial means both to relieve the burden of disease and to help them finding a MiL or to recover it. **Keywords:** MEANING IN LIFE, SUICIDE, NURSING INTERVENTIONS, LOGOTHERAPY, EMOTIONAL DISTRESS, RELIGIOSITY,

"About a third of my cases are suffering from no clinically definable neurosis, but from the senselessness and emptiness of their lives" (1). This quote from Carl Jung, which remains central to modern psychiatry, implicitly incorporates the depressive and suicidal cases whose weight in the global psychiatric casuistry is significant. Accordingly, the WHO has projected depression as the primary cause of global disease burden by 2030 (2), while near 800,000 persons die by suicide every year (3). Given the predicted significant extents and burden of these psychiatric diseases, the therapeutic nursing interventions require further refinements and customizations to deal with the growing mental health problems associated with existential psychological issues of the psychiatric patients affected by loneliness, failure and

emptiness, and who often feel devoid of any MiL. Analysis and understanding of MiL-related beliefs of depressive suicidal patients may improve the mental health outcomes (4).

Life value based therapeutic interventions for suicide prevention emerged from the assumption that people suffering from suicidal ideation have lost any desire to live (5). Different reports on the suicide phenomenon showed that MiL is a key protective factor against suicide attempts, leading to a positive attitude towards life (5-10). Accordingly, suicide-vulnerable people need consistent supportive actions in finding a new meaning in their life or to recover a lost one in order to improve their mental state.

MiL encompasses many complex definitions, but in a simplistic way, for a person with suicidal behavior, MiL might be linked to the following related questions: "Do I still preserve any value, significance, importance or, in short, any meaning for somebody or something in this world? Do I still matter for someone? How useful do I still feel myself for my family, friends or larger society? Have I lost any interest from people on me? How much self-esteem do I still have?". The responses are invariably "no" or "not too much."

From a clinical point of view, studies have underscored in a unitary way the protective impact of MiL on the suicidal ideation, on suicide attempts and completed suicides. The correlations between the search for a MiL and those related to the suicidal state were less consistent, but they were oriented towards a non-protective impact (6). Some studies examining the relationship between MiL and psychopathology have shown that low levels of MiL are associated with mental disorders, addiction disorders, depression, hopelessness and suicide (11).

Viktor Frankl has shown that meaninglessness can lead to depression, addiction and aggression, calling them neurotic triad or existential neurosis (12,13). To address this existential suffering, he developed Logotherapy for his patients, helping them find meaning in their lives and making them aware of the hidden meaning of existence (13). But the best therapeutic approach, according to Frankl, is to ask patients about the meaning of their life (13,14). Consequently, we built the discussions around this particular approach, while the key question about patients' own MiL was addressed directly, albeit carefully and compassionately, in the middle of the conversations. This critical question was placed at the center of the discussion, so as to balance the history of the patient's past and present life experiences with present and potential future actions that could help to better cope with suicide.

Therefore, the objective of this paper was to initiate a dialogue with suicidal patients in order to evaluate their mental state and beliefs related to their MiL. Another objective was to evaluate the potential induced by a friendly supportive discussion, grounded on the mutual confidence built during previous hospitalizations, to get critical confessions about their existential issues associated with beneficial relieving mental states, assuming a cathartic potential of the confessional act.

MATERIAL AND METHODS

Study population and data collection. As a basis for discussions, we have created eleven guiding questions which were addressed to a group of psychiatric Caucasian patients. The patients were recruited from those with multiple hospitalizations in our psychiatric hospital. The target group in-

cluded 31 patients with suicidal behavior while the control group consisted of 31 patients with psychiatric diagnoses from which depression, suicidal behavior, dementia and oligophrenia were excluded. The control patients were diagnosed with schizophrenia, bipolar disorder, organic personality disorder, anxiety disorder, alcohol withdrawal syndrome, sleep disorder. At the time of the conversations, the patients were hospitalized in the same hospital, have been known to the investigator for an average of 4.8 years (median 2.9 years), and were randomly included in the study. No personal or identification data were collected. Participation in this study was exclusively conducted on a voluntary basis and no kind of recompense or favor was offered to patients. The data were collected following a series of individual discussions, initiated only when the patients felt they were prepared for them. From each discussion, we have selected the key confession related to the target question. The confessions were slightly processed, especially grammatically.

Ethical approval. The patients were informed about the subject of the discussions and offered their informed consent. The institutional ethics committee approved the study.

Descriptive statistic. To examine the differences between the two groups, the *Pearson Chi square* test was used. Means and standard deviations were calculated for quantitative variables. The confidence intervals, CI, for proportions were calculated through *Microsoft Excel* 2007. Significance was set at standard $p<0.05$.

RESULTS AND DISCUSSION

Characteristics of the patients are included in first table. The two groups were identically structured, with a women-to-men ratio of about 1.4:1. There was no significant difference with respect to the mean age. The control group included more patients living in rural areas, but the difference is statistically non-significant (p=0.309 CI=0.38-0.71). 80 % of the suicidal patients were diagnosed with suicide attempts.

TABLE I.

Characteristics of the psychiatric patients

Defining characteristics	Suicidal patients		Control patients		Statistical significance	Confidence interval (CI)
	N	%	N	%	p*	95%
Sex						
Women	18	58	*18*	58	1.00	0.46-0.69
Men	13	42	*13*	42		0.3-0.54
Place of residence						
Urban	17	55	*13*	42	0.309	0.36-0.61
Rural	14	45	*18*	58		0.39-0.64
Suicide attempts						
Women	12	39	0	0	1.00	0.11-0.31
Men	13	42	0	0		0.13-0.33
Age (M±SD)	**55 ±13.5**		**58.7±9.7**			
Women	53.5 ± 14.1		57.7 ± 11.3		0.942	
Men	57.1 ± 12.8		60.4 ± 6.5			
* by Chi square test for 5% level of significance						

Table II displays the questions addressed to the two groups of patients. The conversations started with two questions about the importance of the hospital community and the family on their well-being. The following four questions probed their particular psychical state, with an emphasis on their meaning in life, while the next three questions focused on the willingness to help their family and other suffering people as an indicator of their remaining ability to feel useful and, therefore, to have a good reason to continue living. The last two questions sought to ascertain whether religion, prayers, religious activities, and a relationship with God could form a supportive way for these patients. The latter questions were based on an internal survey that showed that more than 90 % of the psychiatric patients are religious (data not published).

The beneficial effects induced by the relationships with other patients and with the medical staff were equally acknowledged by the hospitalized patients. However, the protective role of the family was obvious only for the control group ($p < 0.05$), whereas 35 % of the suicidal patients denied such a role.

A highly significant difference ($p<<0.05$) was noted when asking for their current pleasure to live compared to that felt 5-10 years before. None of suicidal patients responded positively.

The unfulfilled dreams of their life have almost equally affected both groups. It appears that life did not offer those patients compensatory alternatives and opportunities to balance their unfulfilled dreams in order to preserve pleasure, the will and the reason to live at normal levels, which contributes to the failure of their current life. Moreover, by finding themselves now under the roof of a psychiatric institution, often felt as a social stigma, the frustration feeling regarding their unfulfilled life-spanning wishes and dreams was heightened even more.

TABLE II.

Questions addressed to the two groups of patients

QUESTIONS	Responses							
	Suicidal patients			Control patients			Statistical significance	Confidence interval (CI)
	Yes	*No*	*I don't know*	*Yes*	*No*	*I don't know*	*p**	*95 % CI*
1.Do the community of patients in the hospital, the doctors, and medical staff in general, help you feel better?	**29**	2	-	**30**	1	0	0.554	0.86-0.98
2. Does the family help you feel better?	**20**	11	-	**27**	3	1	0.047	0.64-0.85
3. Do you feel that you have the same pleasure to live as 5-10 years ago?	**0**	31	-	**15**	16	-	0.0005	0.15-0.36
4. Have you been very much affected because you could not fulfill certain desires/dreams in your life?	**26**	5	-	**24**	7	-	0.520	0.69-0.88

QUESTIONS	Responses							
	Suicidal patients			Control patients			Statistical significance	Confidence interval (CI)
	Yes	*No*	*I don't know*	*Yes*	*No*	*I don't know*	*p**	*95 % CI*
5. Have you been highly affected / disappointed by what (negatively) happened in your life?	**29**	2	-	**23**	8	-	0.038	0.73-0.91
6. Do you still have any meaning in life?	**8**	22	1	**25**	6	-	0.0001	0.41-0.65
7. Do you think you are or can be useful to your family?	**18**	12	1	**28**	2	1	0.009	0.62-0.83
8. Do you think you are still useful to the others?	**13**	18	-	**31**	-	-	0.0002	0.59-0.81
9. If you had the opportunity to be useful to other people who have different sufferings would you accept to help them?	**28**	2	1	**31**	-	-	0.438	0.87-0.98
10. Do you think an activity in the church dedicated to helping the unfortunate people would help you?	**26**	4	1	**29**	2	-	0.514	0.78-0.94
11. Do you believe that prayer, knowing God and living your faith can give you a meaning in your life?	**26**	5	-	**31**	-	-	0.086	0.82-0.97
* by Chi square test for 5% level of significance								

If the fourth question probed the influence of what the patients dreamt happening in their life, the next question investigated the effect of (negative) events happened in their life. It appeared that negative life experiences affected more patients from the target group (90% *vs.* 74%; p=0.038; CI=0.37-0.31). Considering the medical diagnoses, this is an expected result. It certifies the deeper life sufferings of suicidal patients - generally very sensitive people - who allegedly felt helpless and mentally unprepared to overcome a series of unexpected bad events in their life.

The key question in the discussions concerned the current perception of their MiL. The results showed a significant difference between the groups ($p < 0.05$; CI = 0.41-0.65), most patients from the target group losing any meaning in life (70 %). All of the latter were marked by suicide attempts (tab. I). However, it is worth mentioning that about 20 % from the control group also confessed that they lost their MiL. To recall, they were not diagnosed with depression or suicidal behavior. Hence, since the loss of their MiL is both a specific marker and a trigger for a suicidal behavior, more attention needs to be paid to those patients with undeclared or non-quantifiable signs of suicide behavior. Therefore, questioning psychiatric patients about their MiL may substantially shape the therapeutic approach for a series of cases. Likewise, as Frankl suggested, asking patients about the meaning of their life

would be the best treatment (13, 14).

A significant fraction of the target patients, i.e., 39%, no longer considered themselves useful for their family or were unsure of this (3%). This contrasts sharply ($p = 0.009$; CI = 0.62-0.83) with the control group for which over 90% of the patients believed they were helpful to their families. Almost the same result was obtained when the interest was changed from the family to "other people" (question 8).

Focusing on the target group, it is interesting to note that, while MiL was found as maintained for 26% of patients (question 6), the percentage unexpectedly doubled when their usefulness for the family (question 7) was assessed (58%; $p=0.034$; CI: 0.41-0.74). However, when usefulness was redirected from the family to "other people", the statistically significant difference, with regard to MiL, was canceled (42%; $p=0.352$; CI=0.26-0.59). The results show that patients will feel more stabilized if the family takes into account their support/contribution and acknowledges their meaning/importance in the family life. This underscores the fundamental role of the family in maintaining a MiL for the suicidal patients.

A highly positive attitude was noted when the discussions were directed towards helping other suffering people (question 9). The majority of patients (90 % of the target group) stated their willingness to help these people, as a comprehensive confirmation that suffering deeply sensitizes and unites patients. This is perhaps the reason hospitalization has a healing effect by itself. Accordingly, it can be assumed that, in addition to medication, psychotherapy, ergotherapy or spiritual and religious support, the compassionate confessions exchanged between patients might form a valuable therapeutic means to stabilize their mental state.

Following a survey conducted in our hospital, the majority of patients declared themselves religious (15). Accordingly, the patients stated that engaging in a church activity dedicated to helping suffering people will also help them (question 10), without a statistically significant difference between groups. However, the percentage of those rejecting such a possibility increased slightly for both groups with about 6% as compared to that observed for question 9. The difference is statistically insignificant but might express a tendency to avoid typical restrictive rules imposed by organized social actions, even when conducted under a religious umbrella.

Finally, we also found a dialogue about the possibility that patients' intrinsic religiosity could be considered a means of recovery or finding their MiL to be opportune (question 11). The results showed that prayer, knowing of God and living their faith can afford patients meaning in their life, without a statistically significant difference between the two groups ($p=0.086$; CI=0.82-0.97). However, 16% of the suicidal patients were pessimistic about the help they could receive from God.

Given that 71% of the target patients stated that they no longer had a MiL (question 6), it is remarkable that over 80% of them (question 11) believe that a relationship with God could offer them a MiL. Therefore, the intrinsic religiosity of the suicidal patients should be taken into account a lot more in order to reverse their negative mental state.

Patients' confessions

As Table 3 shows, the patients in each group expressed divergent ideas, opinions, feelings, and desires. The miscellaneous

confessions are most likely the result of their different levels of suffering shaped by type of personality, intellectual condition, self-esteem, life experience, psychological profile, religiosity level, and relationships they used to have with their family, friends, and community. In Table III, the very short responses, e.g., yes/no, were not considered for analysis.

In their confessions, the role of the family as a source of equilibrium and improvement of one's mental state appeared to be crucial for all patients. The lack of the family's emotional support was perceived as a burden difficult to tackle. However, the family itself is being seen as a cause of their difficulties. Patients appeared very affected when the family did not understand their illness and need for communication. They clearly miss the love of the family and suffer from the lack of recognition of their meaning in the family life.

The mental state of patients appeared to degrade significantly quite recently. Or, much likely, they had already been on an accelerating tendency of degrading mental state over the past 5-10 years of suffering. Different causes such as tragic family events, social trauma, betrayals of family members, isolation, lack of shared love, or problems in sexual life quickly degraded their psychological condition. In general, the target patients showed a more depressed condition compared to the control group.

TABLE III

The most relevant confessions during the conversations with psychiatric patients

1. Do the community of patients in the hospital, the doctors, the medical staff in general, help you feel better?	
Suicidal patients	*Control patients*
° The hospital allows me to be isolated from the world, and the personnel respect my desire for minimal interaction. ° In the hospital I can socialize better. I have shared my sufferings with others. I would share my experience every time and I would feel better. ° The hospital gives me the opportunity to talk about topics I know well, to offer advice to and help those who request it. ° Apart from you and the treatment, nobody talks to me. Every time I was hospitalized you stopped to talk to me and asked about me and my illness. Discussions with you made me always feel good. ° The doctors are very important to me because they know more medical information and healing methods than we do.	° Here we can find help, a good word, rest, relaxation, treatment, appeasement, good advice, and good food. ° I like to talk about myself to others, about how I survived cancer, a distressing experience which changed me into an evolved person in many regards. The other patients listen to my life story, and I feel better. ° I felt protected when I came here. ° Here, I get rid of the hard time I usually have at home with my family.
2. Does the family help you feel better?	
Suicidal patients	*Control patients*
° I would like my wife to speak calmly to me, a good word, not to speak to me with contempt, but to be understood, helped. ° My family should believe I am sick, should understand my illness. I miss the love of my family. ° I would like my family to communicate with me through "deeds" and good words, gently, calmly. They have to take me	° I need the love of my family. In the family one is loved and protected. All my life I felt the need for that. ° I need a good word, communication between us. The members of my family do not talk to me. I suffer from this. ° I want to be useful to my family. I cook, wash, and iron the clothes. ° I feel lonely. My family doesn't support or encourage

easier, not to answer back to me; otherwise, I get angry and slam things. ° I want my husband to accept me as I am. ° I want my husband to come to church with me to learn together how to make peace in our lives. ° I don't have to tell anyone what my suffering is. Nothing can help me. ° My wife loved me more in the past. Now, she doesn't love me anymore. I think she has a lover. ° I was exploited by persons close to me. I would have been beaten if I didn't do what they said. So, I don't believe in anyone. ° They don't do anything for me. So, I don't want to do anything for anyone. I want to be useful only to myself. I have 6 years of treatment, and no one can do anything to cure me. Not I.	me. I need their empathy. ° I need my family to understand my situation, to acknowledge my need to know and feel that I am still important to them. ° They simply can't help me. I represent a complicated situation. ° What should I do to be happy? What should I do?! My family can't help me be happy.
3. Do you feel that you have the same pleasure to live as 5-10 years ago?	
Suicidal patients	*Control patients*
° Since my husband fell ill in his lungs, there is no life between two people - sexual life, I mean. There is no love. Because of him my head hurts. You are a woman, and you can understand me, don't you? ° I don't want anything from life anymore. I have no pleasure. Before, I crocheted, watched TV, read. Now, I'm bored of life, with many problems. Many concerns have gathered in my soul. ° I feel helpless. I think I'm useless. I enjoy nothing anymore! I have no expectations, and I feel the need to retire to my carapace. I have no plans for the future. ° I would have liked to be loved, but I wasn't. I would have liked to offer love, but no one wanted my love. This is my real drama. ° I live for myself. I don't want to live anymore. Next time when I decide ° to do something about dying, I'll be more careful not to escape. ° I feel the fatigue and the bad thoughts that press my soul. I am too tired to hang up. ° No, I'm sick now and I'm no longer useful to my family. My wife would like me to work harder, to bring more money. But I can't. You have no value in front of them (i.e., family members, N/A). It can be seen from their words and attitude. ° I don't feel. I don't have that feeling anymore. I do not feel anything. ° After four deaths in my family, I no longer have the pleasure for life I had before. I had nightmares after nightmares. ° Definitely not! I was fooled, betrayed by the family: my mother and my sister. What could be worse in the world than	° I am thinking that I'm alone at home. I am thinking of loneliness. When holidays come, it doesn't seem to be so! Love was lost, everything was lost! I can't even do the fir tree anymore. ° Before, I was more expansive, more joking. I had bigger joys. Now... a lot has happened! I have problems with money. I don't have enough to live on decently. And is my boy that I raised up still on my side? Then, my mother is old. What will I do if she dies? ° Yes, ten times more pleasure! I get my energy from meeting people who have dreams, plans. I have a dream book in which I always tick other and other accomplishments. ° Yes, I have a great love for the grandchildren, and I try to be active, hardworking. I feel excellent, but my physical power diminished, unfortunately. ° I feel joy when I get up in the morning. I want to live my life! ° What could I do to be happy? The treatment does not help me to be happy. It just calms me down. But I'm not happy in my soul. Why has everything changed for the worse?

the mother's betrayal? And even of your only sister? Can you explain this to me, dear lady?! Because I can't understand. You can't even imagine the extent of my suffering. I am still bleeding.	
4. Have you been very much affected because you could not fulfill certain dreams/desires in your life?	
Suicidal patients	*Control patients*
° I wanted to have a job, but my husband did not allow me. I would have done any kind of job just to get out of the house. I sacrificed myself for him and for the children. But he beat me. I did not live a loving life with my husband. ° I wanted my mother and my brothers to love me, but neither my mother nor my brothers received me in their soul. ° I dreamt to be a doctor, but I came out a simple, worthless person, a nurse, not a doctor. ° I dreamed of having a beautiful family. But my wife started drinking a lot of alcohol. Years and years. I wanted to die! Let the bombs, floods come over me only to die. ° I always wanted to be a doctor and to be in the Spanish class, but, unfortunately, the parents chose for me instead; then, they abandoned me and did not understand me.	° I wanted my children to become good-hearted people, with important professional positions, but unfortunately this did not happen. I am disappointed. ° I feel sorry I don't have a child. This is my dream. A child would change my mood and would give me a meaning in life. ° I regret that I did not have a driving license, a hunting rifle and a car. They would have afforded me freedom and confidence. ° I regret that I was not an intellectual. I feel inferior. ° I've made myself a living. I worked at the bus-station, have a small business, cars, family. All my dreams are fulfilled. However, I feel an anxiety in my soul. I can't find peace. ° All my life I wanted to live in solitude, but unfortunately it was not possible. There is no stillness in the monasteries, either. The hospital respects in part my need for loneliness.
5. Have you been highly affected / disappointed by what (negatively) happened in your life?	
Suicidal patients	*Control patients*
° I am very affected. I couldn't trust anyone. Nobody did anything but steal from you, deceive you, pretend to be your friend when actually he was a wolf dressed in a sheep's skin! ° Yes. My wife didn't appreciate those few achievements of mine. She reproached me for my weaknesses, but she didn't see my strengths. ° I had both joys and troubles. I'm not disappointed. ° When I remember that once everything was fine and suddenly everything was reversed! I stopped the treatment and different psychic states began to appear one after another. I treat the agitation, the insomnia appears, I treat the insomnia, and confusions appear. This brain doesn't help me. I can't judge.	° Yes, I didn't have a good relationship with my mother-in-law. I hoped she would be the mother I didn't have, but I was wrong. She didn't love me. I have never known what a mother's love is. Just imagined how it would be. I think she would have understood my suffering. ° Yes, my husband's death traumatized me. It was like the whole world collapsed. All our dreams vanished like a steam. Life is so ephemeral, like a smoke. What does man live and strive for? What is the meaning of life? ° No, I trusted God. No doctor gave me any hope that my boy would live after a very serious road accident in 2011. But I prayed God from all my heart to save him and he recovered. ° No, this is destiny! We must carry it further.
6. Do you still have any meaning in life?	
Suicidal patients	*Control patients*
° No one loves me. What can you do if no one wants you? I am a more withdrawn person while the world is more outgoing. I'm arguing with my wife. She would want a different life, but she doesn't understand my condition, my helplessness. ° No. I was fishing before. It was quiet, it was beautiful. I was happy, content. On the bank of the lake or of the river I was	° I live for my mother to afford her a happy old age and for me not to drink anymore and to solve all my problems. ° The children and grandchildren thank me for having me. I live for them. ° My goal in my remaining life is to get to the people

forgetting about my problems. The water, the fresh air, the sun, the crickets, the birds, all seemed to take the suffering off my shoulders. I was another man after coming back from fishing. Now, my wife doesn't understand me. I'm not fishing anymore. I have to stay with her almost all the time with her endless complains. ° Cold nephews, cold daughter-in-law. I mean nothing in their life or too little. I was good as long as I could help them. I feel isolated and down. Now, I'm sick. I feel a bit better in the hospital than at home, you know? But here there is a lot of suffering. Why is there so much suffering? ° I have reached an age. It's enough. There is nothing like it once was. For my family I do not have much importance anymore. My friends and many dear colleagues died. It's time to leave. I no longer feel joy. Even the food has no taste anymore. ° It's over with my goals in life for a few years. I have finished. There is nothing more to say. ° I want to go to heaven. Not to be tormented anymore! I feel like I can't keep fighting. I feel like something is calling me.	who need me. ° I pray God to give me days to repent for my sins. I have done some wrong things in my life, but I believe God will receive my repentance. I try to correct what I did wrong and help those in need as I can. God is good. I feel this in my heart. All you need is to be sincere in your prayer. God is the goal of my life. ° Yes. I want first of all to do good deeds to the people in order to receive the same. I read once that you are happier when you give than when you receive. It's true. I am content when I am useful to someone. ° Yes. I live for my children. ° I have lost my purpose in life and my faith since my boy died. I don't want to talk about that anymore.
7. Do you think you are or can be useful to your family?	
Suicidal patients	*Control patients*
° To stop drinking. I'm honest. This is how I could help my family. I know, but I can't abstain. I'm not bad, I'm not violent, but I have this problem. I regret. But I had troubles in my life, and I had to drink to forget. ° I think if I were more indifferent… I mean, not to be affected by any minor problem and imperfections of my family. I am a perfectionist, and this led to contradictory discussions with my family. ° Yes, by offering the warmth of my soul to those around me. ° Partially. I feel repulsion. I am closed, non-communicative. ° To work, to have a stable income would be very useful for my family. When you have no work, you get into depression. Family disputes start from lack of money. And I have lived through enough quarrels. I'm tired of everything. ° Yes, I am very useful to the family. I take care of the grand-children, the house. ° Yes, by keeping my calm more and being more open to my family's new ideas and proposal. ° I cannot be useful to the family by any means. I can no longer help anyone. I can't help myself anymore.	° To be positive, to have a sense of humor always created a good atmosphere in the family. I managed to overcome many difficult situations through humor. So does the family. I saw the full half of the glass. From any miserable situation you can learn something good. Don't you agree? Sometimes it is also a lesson you receive from God for your spiritual growth. ° I help them by showing them that I am strong, to raise their morale. Do you know how it is? If I, the one they consider to be sick, show them that I am strong and not afraid of difficulties, then they, who are healthy, must be stronger than me. This is my trick. But they don't know that I'm helping them. I have saved them many times… ° To be respectful towards everyone. That's how I think I help them. ° Yes, by being fair and not troubling them. ° I offer them my love; my good advice and I take care of them. I like to give. ° I would help them if I consumed less alcohol. That's I am here. At least, I am trying.
8. Do you think you are still useful to the others?	
Suicidal patients	*Control patients*
° Yes, I live so I can help others. There are many people more distressed than me. ° I do not think, and I do not want to be useful to others. Kindness costs you dearly. I have learned my lesson! I do not	° Yes. I can offer my knowledge to others. ° Yes. I was glad as much as I have protested against the government. Politicians make laws for their own good. I protested against them to help the poor people.

live for myself, but only so ... only for my tomcat. God does not want to take me. ° No. I think I'm a chore for everyone. I have no power. I can't help them. I'm a big burden. To reach the mercy of the children is very difficult. ° If I were to live, I would help them. ° Very useful. I am a merciful and faithful man. I put myself in their situation. Jesus tells us that what you want people to do onto you, you should do the same onto them. Unfortunately, I was selfish sometimes. But now I'm not anymore. My illnesses helped me understand life differently. I want to help people selflessly. ° No need for me. Everyone is doing well without me. ° I can't, my dear. I have no physical power anymore. I am too old. I am disoriented, confused, and forgetful. ° I cannot. I am too burdened with worries and affected by my husband's behavior; he beats me, he is wicked. ° I don't feel like I have to help anyone.	° Yes, even if I'm not healthy, I can help with a sweet word, some advice. ° Yes, I can help with moral and physical support ° Yes. I have to be. Otherwise, I'm afraid I'm going to hell.
9. If you had the opportunity to be useful to other people who have different sufferings would you accept to help them?	
Suicidal patients	*Control patients*
° Sure. A lot. It would bring me joy. I would always give. Helping and giving is like a medicine to me. ° I'd love to help! Socializing would help me, too. ° It would be useful to me. I feel gratitude in my soul. From my nature, I feel compassion towards those in suffering. ° I would like to help all those who have difficulties in their lives, and I think it would help me a lot. ° Yes. I have given alms with my priest. ° In no case will I help anyone. I helped. I was naive. ° I'm not rich, but I would like to share what I have with others. ° Anytime with a clean heart. Others helped me, too. ° With the greatest pleasure. I felt good, useful. Other people also helped me. My wife doesn't understand me. She wants money.	° Yes, it brings me joy of soul. ° That's why I live. Through everything I do, I share with others what I have accumulated. ° I calm down when I do good things for other people in need. ° I really like a lot to give. ° People helped me when I was in big trouble. It was a time when I had nothing to eat. I lived a humble life. I know what poverty, indigence mean. But people were really good to me. There are still good people in the world. They were merciful to me. Whenever needed, I want to help those who are now like I was once. ° I help old people, orphans, animals. I feel useful. Do you know that animals also have a soul? They feel that I help, and I love them. ° Yes. I have remorse because I can't help as often as I would like.
10. Do you think an activity in the church dedicated to helping the unfortunate people would help you?	
Suicidal patients	*Control patients*
° Yes. It is good to help the sick people also through the Church. When I wanted to commit suicide, I thought of God. I'm afraid of Him. A brother-in-law of mine saved me from drowning. In those moments, God gave me the power to choose life. ° Yes, but the younger Father (priest) of our church disappointed me. He told me: "As you can go to other churches to attend the religious services, you can also come to my	° Yes. When I was in great distress, I wanted to meet people to help me, and the Lord listened to my prayers. I was diagnosed with cancer, and I prayed the Lord to give me days to live to help my children. I prayed Him to do what He thinks is best for me. And so, it was. Many people need God's help. ° We are so many sick and unhappy people. I would participate, but I have nothing to give. God have mercy

church." But I feel bad, and I cannot stay in our church because there are not enough seats. I would go to stay for up to an hour, but I have nowhere to sit. For this reason, it would be hard for me to go with him to help others. But I would go with the older Father. ° Yes. I would help because God helped me, too. I was seriously injured in 2006. I was in the 4th grade coma, and I could have been dead. However, God gave me life to live, but then I did only nonsense. Helping other sufferers would wash my sins. ° Yes. I, as a (psalm) reader in the Church, along with my Father have visited and helped many unfortunate people. Their suffering made us sad, but we felt great peace of soul sharing their troubles and helping them as best as we could. We have seen many tears on their cheeks. ° No. If I want to do good things for other people, I do them alone.	and help everyone who helped me! ° I never participated. But I think it would be great for those in the parish who are sick and have no one else. I would go with other believers to help. I probably would feel good to help them as I can. ° Yes. Sick people understand best the poor fellows. And through the Church it is even better to help one another. Sometimes, God is all we have left.
11. Do you believe that prayer, knowing God and living your faith can give you meaning in your life?	
Suicidal patients	*Control patients*
° Yes. Through prayer and in the Church, I feel free and spiritually fulfilled. I feel as I would be unchained. ° Prayer helped me a lot. I would not have resisted if I had no faith against all the troubles I had. ° It is a very great spiritual joy. I wish to go to the Metropolitan Cathedral and to spend a full day in the Church service. I pray the Lord to give me health, peace, joy. ° No. I insulted God. Anyway, I'll go to hell. ° No. I don't believe in the Church anymore. I want to sell my soul to the devil.	° I'm religious. Even though I have some medical problems, these are because of my sins, and I do not accuse God. On the contrary, I am grateful. Prayer and faith are everything to me. ° I believe that people of faith are everywhere. I help everyone who comes my way. I confess my faith through good deeds that bring me spiritual fulfillment. ° I go out on the road praying. I pray at home. God is with me, bringing peace and safety in my soul. ° Faith keeps me alive. If I experience joy, I feel I have to share it. ° Faith has given me a good meaning in life. The discussions about God cheer my soul. I feel joy in my heart. ° Without God, we don't exist. I have great faith in God. Without the Church we would have no purpose and without prayer we could not live. ° Yes. I have a great faith in God. Although I had myocardial infarction, I had the power to heal myself with the Lord's power. I said: "God, if you exist, as I know you exist, help me when I go to the cardiac control that there will be no sign left." When I went to the hospital, there was no sign of illness anymore. I think you don't really believe me ... but this is it.

Unfulfilled wishes represented a source of inhibitions and humiliations for some patients. They suffered from the freedom limitation, failure in appreciating their sacrifice by their own family, deteriorated family prestige by an alcoholic spouse, frustration and shame generated by not assuming their current professional status,

abuses and lack of protection, or clearly-expressed lack of MiL.

The majority of patients, especially suicidal ones, experienced a series of severe life traumas, mostly occurred in their families, which have continuously influenced their perception towards the people they interact or live with. The deterioration of confidence in people, the loss of any hope of healing, and the inability to overcome some unexpected cold family relationships have constituted long-term triggers for their present mental condition. However, in the control group, some patients found strong support in God or seemed to be mentally stronger in facing the critical events that occurred in their lives.

Patients have expressed some universally-valid motivations for living: to love and be loved, to mean something to their family and/or society, to help and enjoy children and grandchildren, to be useful to the needy people, to live for God, or simply to enjoy life for itself. Degradation of these motivations, corroborated with a mental illness, especially in a geriatric context, can quickly lead to the loss of MiL with consequent suicidal tendencies. In addition, especially for the suicidal patients, narrowing the mentally comforting activities, such as fishing for a particular case evaluated here, due to the inability of the family to understand the psychiatric disease, may be critical in triggering a suicide. Hence, the family should be specifically trained and alerted to the specific needs of these very sensitive patients.

Despite their fragile mental condition, most patients felt that they could be useful to their family, being aware of both their qualities and weaknesses in backing it. Part of the control group revealed an unexpectedly good supportive behavior, expressing their high capability to change the family's mood in difficult situations.

When the focus was shifted from family to other people, things were slightly changed for the target group of patients. It was observed that suicidal patients were less willing to help others outside their family, even if the difference was statistically insignificant ($p=0.286$; CI=0.38-0.62). The reason might include subjective and objective factors such as the absence of affective ties with foreign people, reluctance or even fear of the unknown, physical inability to move to other people, high burden with marriage problems, social disappointments, or feelings of worthlessness.

When the question regarding helping the others included a narrowing feature such as *suffering*, their reaction changed significantly. Suffering by itself immediately sensitized them, showing a high capacity to empathize for majority of suicidal patients. They feel compassion towards people found in conditions similar to theirs, seeing themselves as beneficiaries of these charitable acts rather than as benefactors. Such charitable activities are confessed as bringing them mental peace and satisfaction. The opportunity to help the suffering people has awakened in them the most noble and uplifting human feelings. Overall, involving in helping activities may afford a strong MiL to these patients.

Prayer, the Church and God have proven to be a means of restoring mental balance and releasing internal stresses, affording a good disposition, but also a motivational basis for helping unfortunate people in the case of 84% suicidal patients. God and the Church turned out to be a source of joy and MiL, affording sometimes a strong belief in the divine intervention for healing

the sick. However, some of the suicidal patients rejected God and the Church, though not for atheistic reasons, but as an aversion gained probably from their failures and life problems that were not resolved by divine intervention when they probably prayed for it.

Patients' willingness to participate in volunteer activities coordinated by the Church dedicated to suffering people (related to the last question) were generally grounded on distressing personal experience in which religiosity has played an important supporting role. As a result, participating in such activities was perceived as a moral and religious duty in response to the help they received from God during their traumatic experiences.

The results of the analysis match the theoretical and other empirical findings related to (a) psychosocial characteristics associated with suicide such as loneliness and social isolation (16) which can strongly impact the need for love, (b) family supportive relationships/activities which were also found as very important among patients with and without a non-psychiatric illness (17), (c) religious practices whose positive function is often acknowledged by the general literature, but little described in specific reports focusing on the relationship between health and wellness, and prayer practices (17), (d) prosocial actions (i.e., "acting in ways that benefit others" (18)) which were theorized as MiL sources (19, 20) and empirically validated by Van Tongeren *et al.* (18).

Although the interpersonal theory of suicide does not consider MiL as a significant factor in preventing suicide (22), according to the theory of meaning, the search for MiL make aware people to appreciate the value of their lives, with positive direct outcomes consequences (16, 21, 22). The latter theory was confirmed also by this work, at least in defining patients' current health condition and finding and orienting their future actions in order to improve the mental state.

CONCLUSIONS

In this study, a number of confessions of suicidal patients, mainly related to their MiL, were collected and analyzed. Patients' need to talk about their depressive emotional states, often marked by a painful life experience and unfulfilled wishes and dreams, was perceived as equally intense for both groups. It was revealed that the main reason for living was essentially linked to receiving and giving love, and the need to represent a meaning for someone, especially for family and suffering people. They were especially affected by the corrupted relationships with their own family, as well as by profound negative life experiences in which they felt betrayed, cheated, abused, threatened, despised, or wrongly guided and left alone. As a result, the majority of the suicidal patients lost their meaning in life.

Patients acknowledged the high potential of helping activities to improve their meaning in life by backing other suffering people individually or collectively via Church's community. In addition, they confessed that prayer and living the faith in God would represent mediating motivational values and beliefs to reach a MiL or constitute a MiL by themselves.

Finally, we can state that by recovering the patients from broken family relationships, restoring their love feelings, improving communication and intimate relationships with the spouse, regaining social esteem and trust in people, getting them

involved in volunteering actions to help other suffering people, as well as applying a personalized religious support, a great improve of their mental condition could be possible in order to recover a MiL or to find a new one. Moreover, friendly, compassionate, and empathetic logotherapy of the suicidal patients conducted by the medical staff, performed on a regular basis, might work as a functional integrated platform of medical and social guidance, psychological and spiritual/religious support, and place of relieving confessions.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

ACKNOWLEDGEMENTS.

The authors express their gratitude to Dr. Sorina Chiper, lecturer at the Faculty of Economics and Business Administration, for our fruitful discussions and for editing the manuscript.

NEWS

ARE THE CURRENT SEIZURE SEMIOLOGY CLASSIFICATION AND DESCRIPTIVE DENOMINATIONS WIDELY IMPLEMENTED?

The current way of classifying epilepsy patients is based on a 3-layer approach for the purpose of syndromic refining. In the last 4 years, this has proved to be a limited subdivisional approach failing to take account of the volatility of two aspects, the seizure onset and the temporal relationship of the interconnected structures. A new study published in 2021 in *Epilepsia* proposes an updated model of the neural mechanisms of seizures, framing epilepsy as a partially-defined network in which the clinical expression is secondary to dynamic rhythmic interactions. The correlation of these factors was studied using information coming in the narrative and recorded seizures, the former being prone to inaccuracies. One methodological challenge resides in the inter-observer variability. From the first visit at an epileptologist, each patient can be included in one of the proposed subdivisions, but a caveat for future classification systems would be to properly integrate individualized semiological features (McGonigal A, Bartolomei F, Chauvel P. *On seizure semiology, Epilepsia*. 2021; 62(9): 2019-2035 / doi:10.1111/epi.16994).

EDITORIAL

HEALTHCARE-ASSOCIATED INFECTION

Healthcare-associated infection (HAI), also known as nosocomial infection or intrahospital infection, is one of the major problems of contemporary healthcare worldwide. This notion has evolved over time (1).

The negative consequences regarding the state of health, as well as the high costs resulting from additional care, require the implementation of feasible strategies, with objectives oriented towards the selection of measures to prevent, limit and control HAIs (2).

The etymology of the word "nosocomial" (hospital) comes from the Greek language, the word nosokomeion (νοσοκομειων), where (nosos means disease, and komeo - to care) (3).

Joseph Felsen, a physician in New York, was the first to use the term "hospital epidemiologist" to describe an expert in "investigating outbreaks of infectious disease occurring or spreading within an institution." In a 1939 presentation to the American Public Health Association, Felsen called for the necessity of an epidemiologist in every hospital as part of a comprehensive program to prevent infectious diarrhea (3).

In 1962, New York City's public health authorities created a local hospital epidemiology program (2).

Since 1970s, there has been an increase in the prevalence of HAIs due to the excessive use of broad-spectrum antibiotics and cephalosporins, under the pressure of which multi-resistant microbial strains have been selected (for example, methicillin-resistant *Staphylococcus aureus* - MRSA, extended-spectrum beta-lactamase – BLSE, vancomycin-resistant *enterococcus* - VRE) (5).

The increased prevalence of HAI has been associated with:

- the invasiveness of diagnostic and therapeutic procedures,
- the care of a high number of immunosuppressed patients or patients with diseases,
- the high incidence of infectious pathology of viral or fungal etiology,
- the emergence of emerging infections,
- the neglect of the control system by the failure of the medical staff to observe the standard precautions,
- failure to adapt to HAI surveillance system (6).

The most important clinical distributions are urinary tract infections, surgical wound infections, respiratory tract infections, skin infections, bacteremia.

The infectious disease specialist is facing an increasingly acute problem related to:

a) antibiotic resistance;

b) the presence of multidrug-resistant bacteria in what is another "community infection". This is due to the population mix, the development of the home care sector, patients with multiple comorbidities who have an increased average life span, with survival in the conditions of intensive care and with frequent access to health services;

c) the complicated introduction on the market of a new antibiotic that can take decades

d) the presence of opportunistic germs in immunosuppressed patients, which have become etiological factors of serious sepsis,

bronchopneumonia.

From the experience of the last years, in current practice, we encounter germs that we can call "classics", that have acquired resistance to multiple antibiotics, especially Escherichia coli and *Klebsiella spp.,* which are producing ESBL. Taking this into account, we observed that the cases of resistance to the reserved antibiotics, like carbapenems, are increasingly frequent. Another germ that was panresitent is *Aspergillus fumigatus* that is encountered more often in immunocompromised patients especially HAI in intensive care units (ICU).

In our area, the number of cases of fungal sepsis caused by *Candida spp*. has shown an important increase and there have been a rise in the number of reports for *Candida krusei* and even cases of *Mucor mycosis.* These patients require long hospitalization, antibiotics and antifungals of the latest generation, placement in ICU, support of vital functions, implantation of devices that expose the patient to lingering infections on implanted material and microfilm. All this leads, not only to an increase in the costs of hospitalization, but as well to a decrease in the quality of life of the patients and their relatives. More rigorous control of infections by raising the awareness of patients and family doctors regarding the rigorous use of antibiotics, as well as the persistent and continuous implication of the hospital epidemiologist and the structure he leads, could limit the expand of MDR and panresitent bacteria by checking sanitation measures and correct identification, and reporting of HAI. This would contribute to stopping the phenomena of resistance. In the future, we expect that along with MRSA and BGN-ESBL, we will encounter fungous, as well as atypical mycobacteria, which will lead to a new mutation that will have expensive repercussions regarding the first-line antibiotic-antimycotic-tuberculostatic therapy. All of this will maintain at high levels the consumption of antibiotics and antimycotics of the last generation, with the perpetuation of a vicious circle in terms of multidrug resistance (7, 8).

The prophylactic administration of antibiotics is justified only in special situations, for example in surgical interventions involving the intestinal tract or the repair of traumatic injuries, where the surgical site is contaminated with pathogens (7-9).

The main categories of microorganisms involved in the etiology of HAIs are bacteria (*Clostridioides difficile, Staphylococcus aureus, Pseudomonas aeruginosa, Acinetobacter baumanii, Klebsiella pneumoniae, Escherichia coli),* followed by viruses, fungous, and parasites (5). Compared to the general population, hospitalized patients and immuno-compromised patients (with neoplasia, diabetes, hemodialysis), are much more susceptible to infections. Many patients have a fragile integumentary barrier (surgical or accidental injuries), which is the main way for germs to enter. The lack of intact skin and mucosal integrity provides easy access to infectious agents (10).

Over the past three decades, CDC data have shown that although overall rates of HAI have decreased, antimicrobial resistance of the pathogens involved, and severity of healthcare-associated infections have increased. Measures to prevent and control infections require a detailed knowledge of the epidemiology of the infection (11).

In conclusion, HAIs remain a tangible contemporary reality in all hospital structures. Patients hospitalized in intensive care units, hematology, and oncology departments, those with immunosuppression, premature, dystrophic, catheterized patients, polytransfused patients, or those with long

hospitalization, are the most exposed to nosocomial risk (12, 13).

The problem of HAI is widely recognized and almost all hospitals now have infection prevention and control programs. Hospitals must have programs that include the prevention and surveillance of HAIs, both in patients and in all medical staff. Therefore, each hospital must develop and implement its own procedures and protocols (9).

Due to technical achievements, including in the medical field, the emergence of new molecules, with a life-saving effect in the context of oncological and non-oncological patients, life expectancy in certain categories of patients, especially immunosuppressed ones, has increased. Infections associated with medical care with atypical mycobacteria and fungous are more common among them.

EDITORIAL

THE CHALLENGES OF USING DIRECT ORAL ANTICOAGULANTS IN PATIENTS WITH CHRONIC KIDNEY DISEASE

Direct oral anticoagulants (DOAC) are undeniably a vital pillar of antithrombotic therapy. Dabigatran is a direct thrombin inhibitor that acts by preventing the conversion of fibrinogen to fibrin. Apixaban, betrixaban, edoxaban and rivaroxaban are selective factor Xa inhibitors. Since the first market launch of a DOAC 15 years ago, the number of indications has greatly expanded, based on their superior efficacy and safety in many clinical scenarios compared to classical vitamin K antagonists (VKAs). The indications include prevention of stroke and systemic embolism in patients with atrial fibrillation (AF); prevention of major cardiovascular events in patients with chronic coronary artery disease or peripheral artery disease; treatment of deep vein thrombosis and pulmonary embolism; prevention of recurrent venous thromboembolism (VTE); and prevention of VTE after total knee or hip replacement, or in hospitalized acutely ill medical patients (1). DOACs have several advantages over VKA, such as rapid onset and offset of action, limited food and drug interactions and a wider therapeutic window. They have a stable and predictable effect that allows the administration of fixed doses and does not require monitoring of the anticoagulant effect.

There is a solid bidirectional link between cardiovascular and kidney disease. Not only do they share the same risk factors, such as age, hypertension, dyslipidemia, diabetes, and obesity, but these two diseases are connected by pathophysiological links that allow them to increase each other's incidence and rate of progression in a downward spiral ending in premature heart failure, end-stage renal disease (ESRD) and death.

Individuals with chronic kidney disease (CKD) have an increased risk of thrombotic events, both arterial and venous, with up to half of patients with stage 4-5 CKD being affected during their lifetime. The prothrombotic state is the consequence of complex imbalances affecting the vascular endothelium, platelets and plasma factors of coagulation and fibrinolysis. Toxins related to renal disease decrease the expression and limit the activation of endothelial NO synthase, thereby reducing NO bioavailability and NO-mediated endothelial vasodilation (2). The endothelium becomes activated and expresses adhesion molecules, including the von Willebrand factor, which is responsible for the adhesion of platelets to the endothelium as the first step in generating thrombosis. The functional changes occurring in platelets transform their phenotype into a preactivated one (3). At the level of the damaged vessel wall, the tissue factor is exposed and initiates coagulation and thrombin generation. CKD patients have increased levels of factors V and VIII and reduced levels of antithrombin III, proteins C and S, which favor thrombosis (4). Impaired fibrinolysis is another important factor. The most important change is the increase in fibrinogen and PAI-1 levels. Moreover, fibrin clots

have a dense structure and are less permeable to the action of fibrinolytic enzymes, therefore more difficult to lyse.

CKD patients have a cluster of traditional cardiovascular risk factors, accelerated atherosclerosis and a double prevalence of atrial fibrillation compared to the general population (5). In addition, factors deriving from the presence of renal disease, such as volume overload, albuminuria, abnormal calcium-phosphate metabolism and anemia, also contribute to very high cardiovascular risk. Thus, patients with CKD not only have an increased risk of acute coronary syndromes (ACS) and peripheral arterial disease of the lower limbs but also of ischemic stroke. The greater the decline in renal function and the greater the albuminuria are, the more severe the acute arterial vascular events and the worse the prognosis. The risk of stroke is 5-30 times higher in CKD patients compared to the general population, especially in those on dialysis, and fatal in almost 90% of cases. CKD doubles the mortality rate among ACS patients and ranks third after cardiogenic shock and congestive heart failure as a predictor of mortality (6). A moderate and severe decrease in renal function causes a 2.5 times and 5.5 times increase in the risk of VTE, respectively, compared to normal renal function (7). In addition, the risk of VTE recurrence is 5.3 times higher in CKD patients compared to individuals with normal renal function (8). In dialysis patients - higher in those with hemodialysis than with peritoneal dialysis - the major risk is to develop pulmonary embolism, a risk that is double that of the population without CKD (9).

Patients with CKD not only have an increased risk of thrombosis, but also an increased risk of bleeding. Platelet hypo reactivity is the main contributor. Uremic toxins interfere with platelet-vessel wall interaction, platelet adhesion, aggregation and release of alpha granules, leading to a hemorrhagic phenotype (3). The risk of bleeding increases gradually as kidney function declines. Patients with ESRD have a threefold increased risk of bleeding compared to those without CKD. One in seven patients with stage 5 CKD will experience a major bleed within 3 years of starting dialysis. Of all bleeding sites, hemorrhagic stroke and upper gastrointestinal bleeding are particularly common (10).

As expected, the risk of bleeding increases with the addition of antithrombotic drugs, either antiplatelet or anticoagulant or combination therapy as needed in patients with AF and ACS treated by percutaneous coronary intervention (PCI). Moreover, the difficulty of antithrombotic therapy also lies in the fact that patients with advanced disease, stages 4-5 CKD, have generally been excluded from large, randomized trials or have been underrepresented. When choosing a DOAC for a patient with renal failure, a number of aspects must be considered, such as the severity of renal function decline, the type of DOAC, and the indication (AF or VTE; prevention or therapy).

All DOACs have a renal route of elimination, but there is great variability among them: dabigatran (80%), edoxaban (50%), rivaroxaban (35%), apixaban (27%) and betrixaban (7%). Thus, assessment of renal function is mandatory before initiation of any DOAC and periodically throughout treatment. Moderate or severe renal impairment may contraindicate the use of DOAC or require dose reduction in patients with AF. Dabigatran requires dose reduction at CrCl 30-49ml/min and is contraindicated at CrCl less than 30 ml/min. CrCl is

an essential reference point for establishing the indication for dose reduction in the remaining DOACs. Caution is advised when using low doses of apixaban, edoxaban and rivaroxaban in patients with CrCl 15-29ml/min. In a pooled analysis of patients with AF and stages 3-4 CKD of the pivotal trials of DOAC, all-cause mortality and the rate of all stroke and systemic embolism were slightly reduced by DOAC compared with warfarin (11). In addition, patients receiving a DOAC had less major bleeding than patients treated with VKA, particularly those with stage 4 CKD. Compared with warfarin, patients receiving a DOAC had a trend toward a reduction of intracranial hemorrhage, but slightly more gastrointestinal bleeding. To summarize, DOACs are preferred over VKAs in stages 1-4 CKD, except for dabigatran, which cannot be used in stage 4 CKD (12).

To date, all DOACs have been contraindicated at CrCl less than 15 ml/min (13). The 2020 ESC guidelines for the diagnosis and management of atrial fibrillation state that all DOACs are contraindicated in AF patients on dialysis. However, off-label use has been reported. Increased risk of bleeding was found in patients receiving dabigatran and rivaroxaban (14), but not apixaban (15). Furthermore, dose reduction was considered unnecessary because the composite outcome, including stroke/systemic embolism, major bleeding, and death, was more favorable with a dose of 5 mg bid compared with a lower dose of 2.5 mg bid, especially in terms of stroke prevention (16). New data has recently become available. The RENAL-AF trial published its results in December 2022 and reported that among patients with AF and ESRD on hemodialysis, apixaban treatment had similar rates of bleeding and stroke as warfarin (17). Of note, 71% of patients in this study received apixaban 5 mg bid. Although enrollment challenges led to the premature termination of the study and there was inadequate power to draw any conclusion, one finding should be highlighted, namely, that patients on hemodialysis experienced clinically relevant bleeding approximately ten times more frequently than thrombotic events (stroke cerebrovascular or systemic embolism).

A large meta-analysis showed that DOACs have similar efficacy and better safety than warfarin in preventing VTE recurrence across the spectrum of CKD severity (18). Although rates of intracranial bleeding were similar, DOAC users had fewer clinically relevant major and non-major bleeds than patients receiving VKAs. A systematic review focusing on the prevention of recurrent VTE in CKD patients reinforces these findings (19). Of note, one study showed better efficacy of dabigatran compared to warfarin in elderly patients with moderate renal impairment. DOACs and warfarin similarly reduced the risk of recurrent VTE and had a similar overall risk of bleeding. However, the risk of overall major bleeding from DOACs increased with decreasing renal function, except with apixaban. Additionally, in dialysis patients, apixaban had less overall bleeding compared to warfarin. Based on pharmacokinetic and pharmacodynamics studies, apixaban and rivaroxaban were recently approved by the Food and Drug Administration (FDA) for use in ESRD patients. Furthermore, in patients with VTE and ESRD, a retrospective analysis showed that apixaban has similar efficacy and better safety than warfarin. The incidence of major bleeding, including intracranial and gastrointestinal bleeding, was significantly lower in DOAC users (20).

Another element that differentiates DOACs is the binding to plasma proteins and implicitly the possibility that the drug is dialyzable. Protein binding is strongest for rivaroxaban (92-95%) which is not dialyzable, followed by apixaban (87%), betrixaban (60%), edoxaban (55%) which are partially dialyzable and finally dabigatran (35%), which is the most dialyzable.

A debate is related to the best method of evaluating the renal function, in order to adjust the dose or establish the contraindication for DOAC administration. In patients receiving apixaban, the parameter that defines the renal function is the value of serum creatinine. In patients receiving dabigatran, edoxaban or rivaroxaban, creatinine clearance is used to estimate renal function. The FDA, the highest authority providing guidance to the pharmaceutical industry, recommends that dose adjustment in patients with renal impairment be based on CrCl estimates and explicitly states that the Cockcroft-Gault formula should be used. Therefore, the pivotal trials with DOACs estimated renal function according to this recommendation (21-24). Because the Modification of Diet in Renal Disease (MDRD) and Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) formulas estimate renal function more accurately than the Cockcroft-Gault formula and are widely implemented in current practice, dose mismatches may occur. It was recently shown that approximately 40% of AF patients would have required DOAC dose adjustment if either the MDRD or CKD-EPI formulas had been used instead of the Cockcroft-Gault formula (25). The consequences of this reclassification would have been 5 times increase in the risk of thrombotic events and a numerical increase in major bleeding events. This situation must be known and recognized as very important. Until the academic community and the pharmaceutical industry provide guidance for dose adjustments based on MDRD or CKD-EPI-estimated renal function, DOAC dose adjustments should continue to be made on the basis of renal function estimated by the formula used in the pivotal trials to ensure reproducibility in terms of efficacy and safety of DOAC use.

In the absence of CKD, renal function should be assessed at least annually, and for patients over 75-80 years of age, at least once every 6 months. When CKD is present (CrCl $\leq$ 60 mL/min), the interval between assessments is calculated according to the formula: the number of months = ClCr/10. In addition, renal function will be assessed whenever there is an acute event that may suddenly alter renal function.

We can conclude that the evidence of efficiency and safety of DOAC accumulated in recent years represents a strong ally in the reliable management of anticoagulant therapy in this fragile category of patients, which combines at the same time an increased thrombotic risk, but also a hemorrhagic one. There is increasing evidence that DOACs can be used across the spectrum of CKD.

OBESITY IN WOMEN TREATED FOR BREAST CANCER - CONTROVERSIAL OBSERVATIONS ASSOCIATED WITH MENOPAUSAL STATUS AT DIAGNOSIS (Abstract): Breast cancer is a polymorphic disease, obesity being an important risk factor. The aim of the study is to assess different clinical, imagistic, biological determinants of fat mass and of gonadotropic axis in breast cancer treated patients according to their menopausal status at diagnosis. **Material and methods**: Seventy-eight breast cancer female patients were recruited cross-sectionally. All women were at menopause (physiologic or therapeutically induced). Fat mass was assessed by dual-energy X-ray absorptiometry, and immunoassays were used to determine serum hormones levels. **Results**: Post-menopausal diagnosed women showed statistically significant higher BMI (t=-3.159, p=0.002), abdominal (t=-2.305, p=0.036) and hip circumference (t=-2.683, p=0.009), but not hip/abdominal ratio (t=-0.647, p=0.520); also, they had significantly higher body fat mass (either total, subtotal or trunk fat; $p<0.05$). No statistically significant differences were observed in fasting glucose (t=-0.800, p=0.426), cholesterol (t=-0.566, p=0.573) nor triglycerides (t=0.969, p=0.336). Insulin levels, however, were significantly increased in post-menopausal group (t=-2.420, p=0.018), and subsequently HOMA-IR index assessing insulin-resistance was significantly increased (t=-2.305, p=0.024). Regarding sex hormones, no statistically significant differences were observed in circulating estrogens (estradiol and estrone) nor androgens (total testosterone and calculated free androgen index). However, for both pre-menopause and post-menopause groups, no statistically significant differences were observed in sex hormones according to weight status (obese *vs* non-obese). **Conclusions**: There is significant difference between weight status and risk of breast cancer regarding menopausal status, many reports showing that obesity is a risk factor in post-menopause patients and a protective factor in pre-menopause women, underlying the polymorphism of breast cancer disease. **Keywords**: BREAST CANCER, OBESITY, MENOPAUSE.

Obesity is a disease characterized by excess amount and/or unhealthy distribution of body fat (1). According to the World Health Organization (WHO), excess

weight in adults is characterized by a body mass index (BMI, calculated as weight measured in kilograms divided by height measured in meters squared) ≥ 25.0 kg/m^2, including obesity with a BMI ≥ 30.0 kg/m^2 and overweight status with a BMI between 25 - 29.9 kg/m^2 (1). Excess weight is thus divided into two categories: overweight and obesity.

Compared to people with normal weight, overweight or obese patients have an increased risk of developing multiple diseases, the most common being diabetes, cardiovascular diseases, and cancer (at least 13 types of cancer are being associated with obesity including breast cancer, colorectal cancer, renal cancer, liver cancer, ovarian cancer, multiple myeloma, meningioma) (2-8).

Breast cancer is by far the most common neoplasm among women, with approximately 2.26 million new cases diagnosed in 2020 (24.5% of cancer cases). It is also the most common cause of cancer death in women (15.5%, 684,996 deaths), ranking fifth place globally after the cause of death by cancer (following lung, colorectal, liver, and gastric cancers) (9). Of these, 23.7% of breast cancer cases and 20.7% of deaths were reported in Europe, although Europe has only 10% of the world's female population. In Central and Eastern European regions, 158,708 new cases and 51,988 deaths from breast cancer were reported, representing 29.9% of newly diagnosed cases but 36.3% of deaths caused by this type of tumor (9).

In Romania, 12,085 new cases of breast cancer and 3,918 deaths were reported in 2020, accounting for 2.27% of new cases and 2.4% of deaths attributed to breast cancer in Europe, and 8.5% of newly diagnosed cases but 7.6% of reported deaths for the central and eastern European region (9). A study (10) that analyzed differences in breast cancer mortality in Romania compared to the European Union (EU) over a period of 10 years (from entering EU, 2007-2016) showed a greater increase in the number of deaths caused by breast cancer in Romania, a trend of increasing mortality (opposite to that in the EU) and a reduction in life expectancy that gradually increased from 0.45 years in 2007 to 0.48 years in 2016 (Romania already having one of the lowest life expectancies in the EU, at 76.8 years, 5.4 years lower than the European average) (10).

WHO European Regional Report on Obesity in 2022 estimated that only in Europe, obesity is directly responsible for at least 200,000 new cases of cancer annually and this value is projected to increase in the coming decades (6). In 2012, globally, 33% of breast cancer cases (in postmenopausal women) were attributed to excess weight and obesity totaling 110,000 cases of which 28,000 could have been prevented if average BMI values in general population remained constant since 1982 (11).

Breast cancer is a polymorphic disease, and the current investigation has the objective to assess the differences of different clinical, imagistic, biological determinants of fat mass and of gonadotropic axis in breast cancer treated patients according to their menopausal status at diagnosis of the disease.

MATERIAL AND METHODS

Seventy-eight breast cancer female patients were recruited cross-sectionally. All women were at menopause, either physiologic or therapeutically induced (in function of when the cancer was diagnosed: pre-menopause or post-menopause). Fat

mass was assessed using dual-energy X-ray absorptiometry (DEXA); data recorded included total fat mass, subtotal fat mass (without head region) and trunk fat mass measured in grams (g) or as percentage (%) of total body mass. Immunoassays were used to determine serum hormone levels of insulin, FSH (follicle stimulating hormone), estradiol, estrone, total testosterone. Fasting glucose, total cholesterol and triglycerides were also measured. Insulin-resistance was calculated by HOMA-IR index, and the free testosterone was assessed by determining FAI (free androgen index).

All statistical analyses were performed using *SPSS Version 24.0* software (IBM Corp., Armonk, NY, USA). Associations between continuous variables were analyzed using Spearman correlation coefficients. The level of statistical significance was established at $p<0.05$.

Ethical approval was obtained from the Ethics Committee of "Grigore T. Popa" University of Medicine and Pharmacy Iasi (no. 1642/25.01.2017). The research protocol was approved by the institutional ethics committees of "Sf. Spiridon" County Clinical Emergency Hospital Iasi (no. 78/21.12.2016) and "Grigore T. Popa" University of Medicine and Pharmacy Iasi.

RESULTS

Seventy-eight female patients evaluated at the Endocrinology Department for metabolic or endocrine disease associated to breast cancer treatment were included in the current analysis. Patients had a mean age of 53.3 ± 11.6 years (age between 35-78), among which 45 were diagnosed with breast cancer before menopause, and 33 patients after the menopause. However, all patients were at menopause (physiological or induced) at the moment of assessment.

The group of women diagnosed pre-menopause had a mean age at assessment of 47.5 ± 9.5 years old, being diagnosed at a mean age of 41.6 ± 7.8 years, with mean years of disease of 5.9 ± 5.6 years. They had a mean duration of fertile years (between menarche and induced menopause) of 28.8 ± 7.7.

Women diagnosed after menopause had a mean age at assessment of 61.2 ± 9.3 years old, being diagnosed at a mean age of 57.9 ± 9.3 years, with mean years of disease of 3.4 ± 3.6 years. They had a mean duration of fertile years (between menarche and physiological menopause) of 33.6 ± 4.6.

Morphometric parameters analysis showed that patients did not have a significant difference between height ($t = -0.436$, $p = 0.664$), however the weight was higher in post-menopausal diagnosed patients ($t = -2.8$, $p = 0.006$), determining subsequent variations in BMI ($t = -3.159$, $p= 0.002$). According to the WHO classification of weight status by BMI, in the group of women diagnosed pre-menopause: 57.8% had normal weight (n=26), 28.9% were overweight (n=13) and 13.3% obese (n=6). Post-menopausal group comprised of 36.4% patients with normal weight (n=12), 27.2% overweight (n=9) and 36.4% with obesity (n=12) (fig. 1).

Abdominal circumference ($t = -2.305$, $p = 0.036$) and, also, hip circumference ($t = -2.683$, $p = 0.009$) varied significantly in the two groups, however not the hip/abdominal ratio ($t = -0.647$, $p = 0.520$). The same thing was valid also for fat mass, either total, subtotal or trunk fat mass ($p<0.05$).

Regarding biological parameters, no statistically significant levels were observed in fasting glucose ($t = -0.800$, $p = 0.426$), total cholesterol ($t = -0.566$, $p = 0.573$) and triglycerides ($t = 0.969$, $p = 0.336$) levels between the groups.

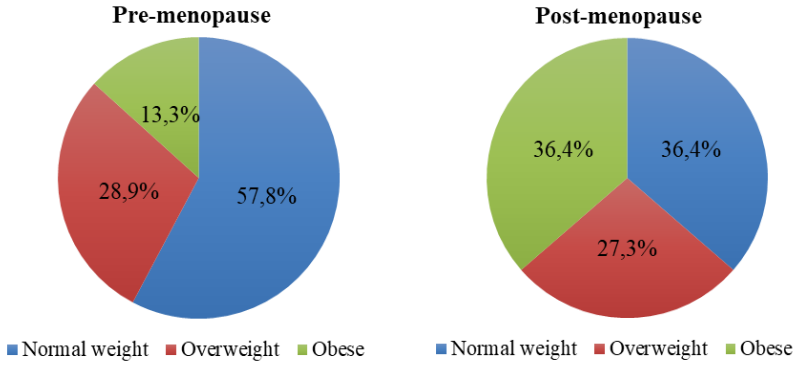

Fig. 1. Distribution of breast cancer cases in pre-menopause (right) *vs.* post-menopause (left) patients according to weight status

However, when analyzed, insulin levels were significantly different (t = -2.420, p = 0.018) in the two groups, pre-menopausal diagnosed women had a lower mean insulin level (9 ± 5.9 µUI/mL), than post-menopausal diagnosed cases (14 ± 11.8 µUI/mL), and subsequently the HOMA-IR assessing insulin-resistance (normal insulin-sensitivity when HOMA-IR below 2) was significantly different (t = -2.305, p = 0.024): in the pre-menopausal group HOMA-IR was lower (mean of 1.8) than in post-menopausal group (mean of 3.2).

Regarding ovarian function, even if all patients were at menopause at the moment of assessment, a difference was observed in FSH levels, as pre-menopausal diagnosed women had a lower mean FSH levels (33.1 mUI/mL), than post-menopausal diagnosed cases (53.4 mUI/mL), statistically significant (t = -2.899, p = 0.005). Estradiol levels measured in these groups showed slightly elevated values for what is normally considered in menopause (normally below 30 pg/mL): pre-menopausal diagnosed group had mean estradiol levels of 53.38 pg/mL, and post-menopausal group of 50.6 pg/mL, however not statistically significant different (t = 0.233, p = 0.817). Similarly, estrone levels also varied between the groups, but not reaching the statistical significance of $p<0.05$ (t = 1.870, p = 0.065): pre-menopausal group had a slightly higher mean value (84.9 ± 39.9 pg/mL) that the post-menopausal group (70.3 ± 25.3 pg/mL). Testosterone levels assessed by total testosterone (t = -2.899, p = 0.005) or as calculated free androgen index (t = -2.899, p = 0.005), were not significantly different between the two groups.

However, for both pre-menopause and post-menopause groups, when checked for differences in sex hormones according to weight status (obese *vs.* non-obese) no statistically significant differences were observed.

DISCUSSION

The major confirmation was that post-menopausal diagnosed women had significant higher fat mass indicators (BMI, abdominal and hip circumference, and quantity of body fat mass in all regions, assessed by DEXA). Even if the number of subjects included in the current analysis was small,

the data is concordat with global results.

Worldwide, the incidence of obesity has almost tripled since 1975 reaching pandemic levels (12). In Romania, available epidemiological data from 2007-2008 (13, 14) estimated a prevalence of overweight of 30-36% of the adult population and obesity of 20-25% (13, 14), with similar values reported in 2015 (15). WHO European Regional Report on Obesity 2022 placed Romania among countries with over 55% of the adult population being overweight and where more than 20% of the population is obese (6). Excess weight has a higher prevalence in men compared to women. In Romania excess weight has a lower prevalence of 51.1% in women compared to 64.3% in men (average prevalence in both sexes of 57.7%); on the other hand, obesity has a higher prevalence in women, of 23.4%, compared to 21.6% in men (average prevalence of obesity in both sexes of 22.5% in Romania, assessed by BMI) (6)We reported the differences between weight and gonadotropic axis in a cross-sectional analysis of female patients treated with breast cancer.

The association between excess weight (overweight/obesity) and breast cancer risk was reported to vary depending on menopausal status, with multiple studies showing a negative correlation between obesity and this risk in premenopausal women (16-18). Van den Brandt *et al.* (19) conducted an analysis of 7 prospective studies totaling a cohort of 337,829 women, of whom 4,385 were diagnosed with invasive breast cancer, finding that in pre-menopause women with a BMI over 31 kg/m^2 have a relative risk (RR) of 0.54 [95% confidence interval (CI 95%): 0.34-0.85] of developing breast cancer compared to those with a BMI below 21 kg/m2 (19). In 2001 Bergström *et al.* (20) conducted another meta-analysis including 9 studies also demonstrating an inverse correlation between obesity and increased BMI regarding breast cancer risk in premenopausal women (RR: 0.98; CI 95%: 0.97-0.99) (20). Renehan *et al.* (19) presented similar results in a meta-analysis consisting of 34 studies (totaling over 2.5 million women) that investigated breast cancer risk in relation to BMI (21). In total breast cancer was reported in 7,930 premenopausal women and 23,909 postmenopausal women. Breast cancer risk was reduced by approximately 8% per 5 kg/m^2 increase in BMI in premenopausal women (RR: 0.92; CI 95%: 0.88-0.97; p=0.001); on the other hand, in postmenopausal women breast cancer risk was increased (RR 1.12; CI 95%: 1.08-1.16; p<0.0001) (21).

The largest and most recent study investigating the association between obesity and breast cancer was conducted by the Premenopausal Breast Cancer Collaborative Group in 2018 (22). This multicenter study included 758,592 premenopausal women aged 18-54 years. They were followed for a median period of 9.3 years, during which 13,082 cases were diagnosed with breast cancer. The analysis showed that underweight women have a 4.2 times higher risk of developing breast cancer than obese women under the age of 24 and a 1.9 to 2.5 times higher risk in women over this age. Taking these results into account, the authors determined an estimated reduction of 12% to 23% in premenopausal breast cancer risk with a 5 kg/m^2 increase in BMI depending on age. Breast cancer positive for estrogen (ER) and/or progesterone receptors (PR) was associated with BMI in all age groups while hormone receptor-negative breast cancer was associated with BMI only in women aged 18-24

years. In this younger age group, the strength of the association between ER and/or PR positive breast cancer and BMI (HR: 0.75; CI 95%: 0.70-0.81) was much stronger than that for hormone receptor-negative breast cancer (HR: 0.85; CI 95%, 0.76-0.95) (22). The lack of association of triple-negative breast cancer with BMI in women over 25 years was contrary to previous reports (23). The authors considered that the discrepancy possibly reflects differences in study design (case-control versus prospective study), the former being more susceptible to potential selection bias (22).

Unlike women of reproductive age, several large studies and meta-analyses have demonstrated a direct and consistent association between obesity and breast cancer risk in postmenopausal women. The Million Women Study (24) followed 1.2 million women in the UK (including 45,037 cases with breast cancer) aged 50-64 years for a median period of 5.4 years. The study identified a risk about 30% higher for breast cancer in obese women compared to non-obese women (RR: 1.29; CI 95%: 1.22-1.36) in the postmenopausal period (24). These findings are comparable to those of Renehan *et al.* (21), previously described (breast cancer risk in postmenopausal women was positively associated with each 5 kg/m^2 increase in their BMI: RR: 1.12; $p < 0.001$) (21).

Local and systemic changes are hypothesized to support the relationship between obesity and breast cancer, including increased circulating levels of insulin and glucose as well as adipose tissue-derived estrogens, adipokines and inflammatory mediators (25).

Subsequent to increased fat mass, insulin levels and HOMA-IR (insulin-resistance) were significantly increased in post-menopause diagnosed women, and not pre-menopause breast cancer cases. No changes were observed with fasting glucose, total cholesterol, or triglycerides between the groups.

Also, no statistically significant differences were observed between circulating sex hormones levels in the two groups. All cases were at menopause and the only difference was in FSH levels; even if it was increased (considered inhibiting for the ovarian function), it was still lower in patients diagnosed with breast cancer in pre-menopause than in women with breast cancer after menopause, possibly in accordance with the number of years since the menopause occurred.

Given the impact of obesity on the development and progression of breast neoplasm, the recommendation is for overweight women to avoid weight gain during treatment and for obese women to lose weight immediately after treatment (26, 27). In the meta-analysis conducted by Chan *et al*. (28), which analyzed 23,182 deaths from 213,075 breast cancer survivors confirmed that the current indication for breast cancer patients is to remain as much as possible within the normal weight range (28).

CONCLUSIONS

Obesity and breast cancer are often associated; however, there is a significant difference between weight status and the risk of breast cancer regarding menopausal status, many reports showing that obesity is a risk factor in post-menopause patients and a protective factor for breast cancer in pre-menopause women. Our result show that post-menopause breast cancer patients present increased fat mass parameters,

insulin levels and insulin-resistance, compared to women diagnosed in premenopause, underlying the polymorphism of breast cancer disease.

URTICARIA IN CHILDREN-A DISEASE IN DISGUISE (Abstract): Urticaria is considered a multifactorial condition, initializing or triggering chronic conditions with dermal or/and hypodermic localization, more common in children and young people. **Material and methods:** A number of 87 children were considered in a retrospective study aiming the diagnostic of acute and chronic urticaria, evolutive particularities and immunological aspects of the allergic condition. Descriptive analysis and correlation with biological parameters of the immunological status (total IgE, allergen-specific Ig E IgA, IgM, IgG) were performed. **Results:** The age distribution showed that most children aged 10-15, with a balanced gender distribution (59.57% male *vs.* 40.43% female patients). Immunological profile associated immune deficiency (IgA and IgG, a minority of patients presenting deficiency of IgM). Elevation of IgE values were found in 9% of cases. Low serum levels of Ig G, A, and M associated clinical features such as upper respiratory infection, gastroenteritis, and otitis media. Four patients with multiple immunoglobulin deficiency and 5 cases with single immunoglobulin deficiency were noticed, including a complete IgA deficiency. Arthritic impairment was observed in 10% of cases. **Conclusions:** Various immune deficiencies were found in children with acute and chronic urticaria. Prospective research is needed to clarify the real role of triggers in the pathogenesis of urticaria and their relative prevalence, in order to apply, with greater accuracy, prevention methods in children at risk. **Keywords**: URTICARIA, CHILDREN, IMMUNO-GLOBULINS.

Allergic diseases can be considered systemic disorders, regarding the polymorphism of the general causes, the associated symptoms and the simultaneous damage to several organs and systems (1). From food allergies with digestive impact to sensitivity to aeroallergens with the atopic cascade towards bronchial asthma, this pathology has aroused the interest of specialists from all fields (2). Nowadays, urticaria is considered to be, in fact, a multifactorial condition, initializing or triggering chronic conditions with dermal or/and hypodermic localization, more common in children and young people. Particularly, less common causes of urticaria, other than allergic agents, aroused specific interest in identifying and interpreting this symptom along with infectious, autoimmune and idiopathic conditions in pediatric patients (3).

The constant concern of allergologists to study the pathogenesis of the disease, the

evolution of clinical manifestations, the biological pattern, but also the evolutionary complications of urticaria confirm the importance of the early implementation of treatment methods (4). Pathogenic and symptomatic medication can momentarily improve the clinical status, but long-term surveillance of these cases is essential, in the event of silent complications that may appear (autoimmune diseases, infection, chronic evolution) (5).

In the present study, we tried to capture the clinical and evolutionary characteristics of children urticaria, a category of patients in which studies of prevalence and etiology are still poor from an informational point of view. For this reason, specialists can take into consideration the ethics of research on pediatric subjects, as well as the reluctance of parents or relatives to be co-opted in clinical trials, and last but not least, the impossibility of exhaustively extrapolating the results obtained in studies conducted on adult patients.

MATERIAL AND METHODS

Study group

A number of 87 children were considered in a retrospective study aiming the diagnostic of acute and chronic urticaria, evolutive particularities and immunological aspects of the allergic condition, other than an allergic-induced trigger. Patients were hospitalized in the Allergology Clinic of the "Sf. Maria" Emergency Clinical Hospital for Children Iasi in a 2-year interval of time. In order to systematize the ideas derived from the study of the material represented by the documentation of the evolution of cases, authors aimed the following objectives:

1. Analysis by observation and correlation of some reference parameters for a representative study group, in which the diagnosis was accurately established and the provision of clinical and biological surveillance in dynamics.

2. Descriptive analysis of the study group for the main defining essential epidemiological parameters: distribution by age groups, gender, distribution according to the type of the disease, distribution according to the associated pathology with acute respiratory disease, also the distribution according to evolutionary complications in the patients included in the present study.

3. Correlation with biological parameters of the immunological status, performing blood sampling to measure total IgE, allergen-specific Ig E IgA, IgM, IgG.

RESULTS

Descriptive analysis

Most of the children were admitted in acute phase of the urticaria, almost 88% of the total of patients, the remaining percentage being assigned to chronic cases of urticaria (fig. 1).

It is rather difficult to assess the chronic status of urticaria, regarding the timing of the rash (appearance, evolution pathway, aspect, associated signs and symptoms), but also determining the minimum six weeks interval of time that is necessary for defining chronic urticaria. In some cases, we can also discuss the possibility of a second allergen involvement, with a new rash appearing, or even multiple triggers (allergens, medicines, stress etc.).

The age distribution showed that most cases were in 10-15 years old children, on behalf of chronic urticaria (fig. 2). Hormonal changes within the adolescence and the possibility of triggering autoimmune diseases, or even the similarity with other pathological conditions are the facts that can enhance allergy status in this age group.

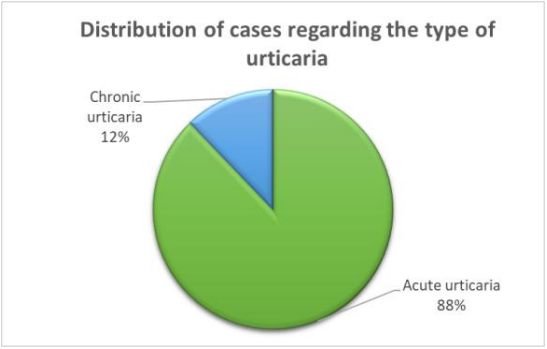

Fig.1. Distribution of cases regarding the type of the urticaria

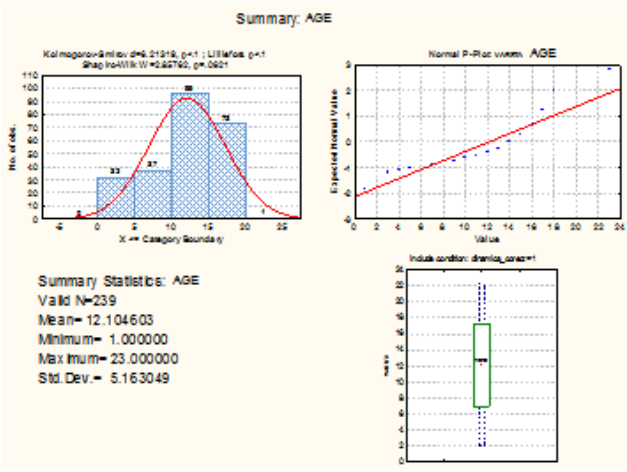

Fig. 2. Histogram of age for the patients with acute and chronic urticaria

Gender distribution was rather balanced, with a slight deviation in favor of male patients (59.57% versus 40.43% female patients). This situation can be explained by the fact that males are more prone in developing, enhancing and transmitting the atopy (in a genetic pathway related to Y chromosome).

Immunological findings

Immunological profile of the patients associated also immune deficiency (Ig A and Ig G, a minority of patients presenting deficiency of Ig M). Elevation of Ig E values were only found in 9% of the cases, leading to the possibility of involving non-atopic mechanisms in the pathogeny of urticaria (fig. 3).

Low serum levels of immunoglobulins G, A, and M were also associating outstanding clinical features of each group - upper respiratory infection, gastroenteritis, and otitis media. In 9 cases, immunoglobulin E levels were above the normal range for age for the laboratory. Four examples of multiple immunoglobulin deficiency and 5 examples of single immunoglobulin deficiency were noted, including a complete IgA deficiency.

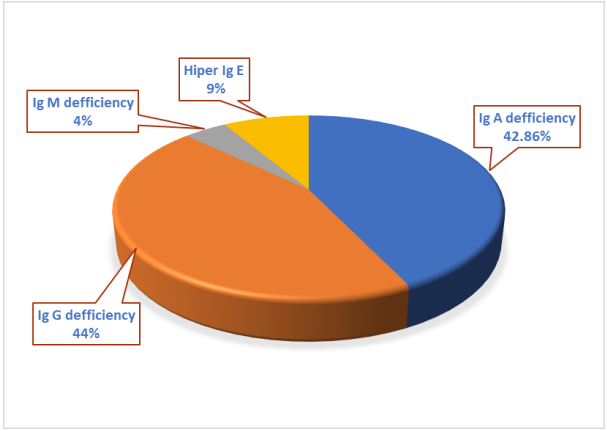

Fig. 3. Immunological findings in patients with acute and chronic urticaria

Atopic and non-atopic associated conditions were determined in the study group, most of cases presenting other allergic manifestations (allergic rhinitis, bronchial asthma, cow s milk allergy, histamine intolerance). Arthritic impairment in selected cases was also observed in a minority of cases (fig. 4). The discussion regarding the obesity versus malnutrition in allergic patients leads to considering food allergy, gastroesophageal reflux and/or autoimmune inflammatory bowel disease to be ruled out in differential diagnostic. Adipokine involvement in determinism of chronic urticaria should be further assessed also in obese pediatric patients.

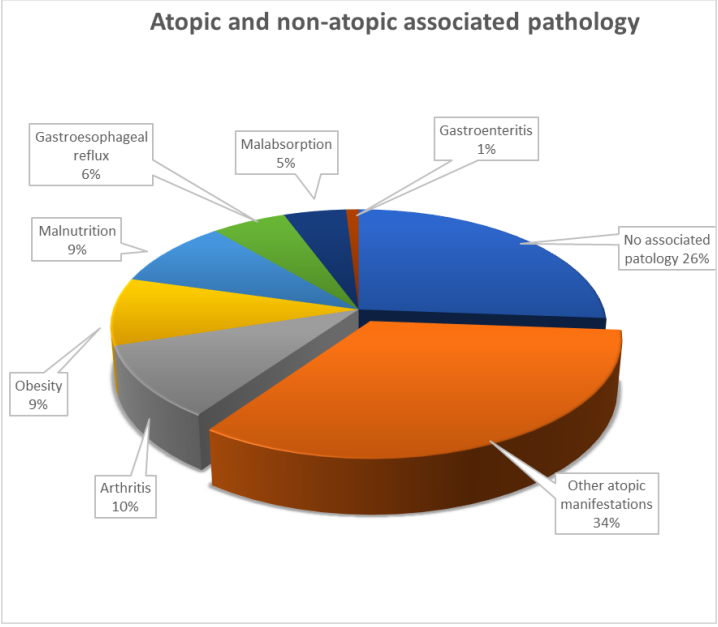

Fig. 4. Associated pathologies in children with urticaria

DISCUSSION

Many bacterial infections have been associated with urticaria manifestation, such as those due to *Helicobacter pylori*, *Streptococcus*, *Staphylococcus*, *Mycoplasma pneumoniae*, *Salmonella*, *Brucella*, *Mycobacterium leprae*, *Borrelia*, *Chlamydia pneumoniae*, and *Yersinia enterocolitica*. In some cases, the skin manifestations, falsely considered as urticaria, the presence of the microorganism containing toxins, or the complement activation mediated by circulating immune complexes were, in fact, the trigger factors for the skin rash (6).

This is the case of a young male patient hospitalized with rash and fever, associating cough and alteration of the general status, in which case a bronchial lavage culture revealed the presence of *Mycoplasma pneumoniae* (fig. 5).

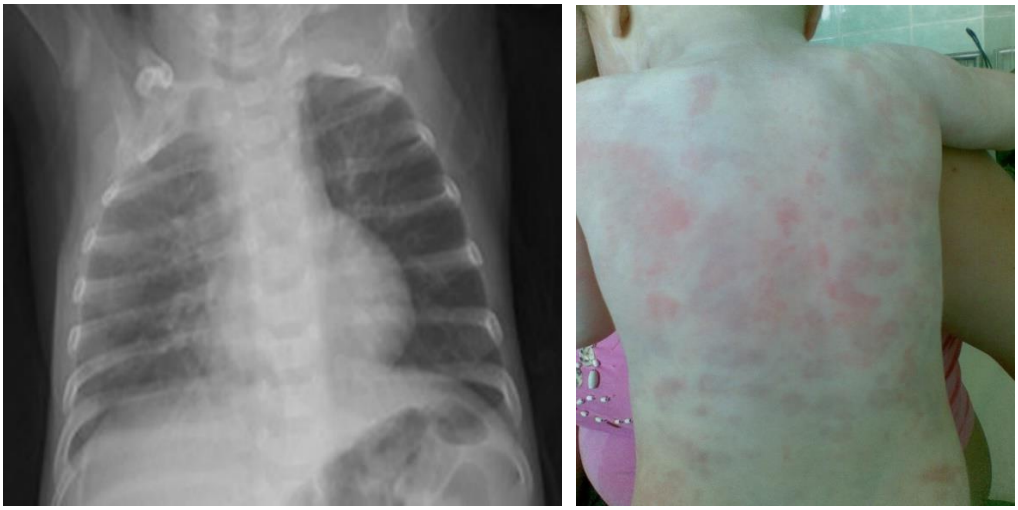

Fig. 5. Male patient, 18 months old, with *Mycoplasma pneumoniae* infection and urticaria

Urticaria may appear also as prodroming various infectious diseases, as seen in one of the patients (female patient, 8 years old) included in the study group (fig. 6).

In this case, the presumed urticarial manifestation was, in fact, a pre-icteric complication of a viral hepatitis, being pathogenically linked to the deposition of circulating immune complexes at the level of the dermis and being frequently associated from a clinical point of view with arthritis and headaches (Caroli's triad). However, an obvious causal relationship between the occurrence of urticaria and chronic viral hepatitis infection has not been objectified. In the case of hepatitis B virus (HBV) and hepatitis C virus (HCV) infections, eruptions are cited as extrahepatic manifestations, but these are probably more related to the underlying vasculitis than to actual urticaria (7). Many patients with urticaria and angioedema were diagnosed with chronic infection with HBV, the markers of hepatitis infection being detected by chance or following subjective accusations that required testing (8). Unlike them, anti-HCV antibodies are less frequent among those diagnosed with urticaria and/or angioedema, according to existing studies in the specialized literature, so we

cannot speak of a significant association between the two conditions. If routine testing for HCV in patients predisposed to eruptions or angioedema does not appear to be effective, viral markers for chronic HCV infection should be sought in these patients.

Fig. 6. Female patient, 8 years old, with chronic urticaria and hepatitis C

Urticarial vasculitis was not identified in the absence of typical clinical features. Food allergy was encountered in a small number of patients and clinical significance was found in the subgroup of patients with positive history of allergy to related foods. Also, intestinal parasitic infestation was found in 5% of children with chronic urticaria, but the clinical correlation could not be established. Several studies demonstrated that 21% of patients with chronic urticaria had no laboratory abnormality. Chronic autoimmune urticarial was identified in more than one-third of children with chronic urticaria, without protracted clinical course. However, a long-term follow-up would be important to identify any association of CAU and other autoimmune diseases (9).

Chronic urticaria-like lesions may also appear in systemic lupus erythematosus (SLE), cases in which the manifestation of chronic urticaria is diverse and often characterized by flares and remissions, and there may be an overlap between clinical features of chronic urticaria and SLE. Alt-

hough patients with acute or chronic urticaria usually do not exhibit LE-specific skin lesions and do not meet the diagnostic criteria for SLE, urticaria may represent the first complaint in these patients before the more classical form of SLE manifests. Urticaria and SLE may have similar cutaneous manifestations, and both are related to immunopathological conditions; however, few studies have examined the effects on SLE of a history of urticaria.

Abnormally low immunoglobulin levels were found in 6 immediate family members (representing 2 of the studied families), and there were also frequent positive family histories of allergy, repeated infection, and collagen disease within the second and third generation relatives. These findings suggest that abnormal immunologic function with resultant repeated bacterial infection may be causally related to the development of urticaria in certain individuals, and that chronic urticaria may be the presenting clinical manifestation of an immunologic-deficiency state.

CONCLUSIONS

Urticaria is one of the most common skin diseases, and pediatric patients may present with a wide spectrum of symptoms, including sudden development of pruritic wheals or angioedema. Chronic urticaria has a significant impact on quality of life due to the constant sensation of itching, regular recurrence, and unknown etiology. Chronic urticaria is diagnosed when disease has been continuously or intermittently present for at least 6 weeks. The chronic and acute forms of urticaria differ in etiology, pathophysiology, and underlying mechanism, being hard to assess mostly in early age.

Previous studies have reported that chronic idiopathic urticaria is associated with infection, pseudo-allergy to a food, autoimmunity or other condition. However, there is little information on the relationship of chronic urticaria developing with non-allergic triggers in children. The association with infectious disease, such as viral and bacterial determined rash, was previously assessed in young children, whereas pneumonia, pharyngitis, gastroenteritis and other diagnostic status created challenges in investigating and treating the patients.

Although only a weak association with urticaria of unclear pathogenesis exists, clinicians should consider these bacterial agents, autoimmune factors or pseudo-allergens in the workup of the patients with urticaria. Prospective studies and well-structured research are obviously needed to better clarify the real role of non-allergic triggers in the pathogenesis of urticaria and their relative prevalence.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

THE ENIGMATIC PROFILE: UNRAVELING CLINICAL AND BIOLOGICAL FEATURES IN COVID-19 PATIENTS (Abstract): The outbreak of COVID-19, caused by the novel coronavirus SARS-CoV-2, has emerged as an unparalleled global health crisis, affecting millions of lives worldwide. This respiratory illness exhibits a wide spectrum of clinical presentations, ranging from mild flu-like symptoms to severe acute respiratory distress syndrome (ARDS), leading to high morbidity and mortality rates, especially among vulnerable populations. In this abstract, we provide a concise overview of the clinical and biological characteristics observed in COVID-19 patients. **The aim** of this study was to evaluate patients with COVID-19 presenting with mild to moderate clinical and paraclinical features and their subsequent outcomes. **Materials and methods:** The study group included 200 patients diagnosed with confirmed COVID-19, exhibiting mild to moderate symptoms, who were admitted for treatment and health monitoring. **Results:** The estimated risk of SARS-CoV-2 infection was over 5 times higher in asymptomatic afebrile patients (RR=5.82; 95% CI: 0.88-38.65; p=0.004). Among asymptomatic patients, C-reactive protein (CRP) levels ranged from 0.58 to 39.88 mg/dL, while in symptomatic patients, the range varied from 0.20 to 200.17 mg/dL. The mean level of CRP was significantly higher in symptomatic patients (13.67 *vs.* 5.73 mg/dL; p=0.001). Regarding imaging examinations, 38.6% of subjects did not show pathological aspects. The time to viral clearance ranged from 9 to 41 days in asymptomatic patients and from 2 to 38 days in symptomatic patients, with a similar mean duration in both groups (18.71 *vs.* 18.79 days; p=0.936). **Conclusions:** The estimated risk of SARS-CoV-2 infection was over 5 times higher in asymptomatic afebrile patients, and among laboratory markers, the inflammatory marker CRP was associated with a more severe COVID-19 outcome. Our study has several limitations that need to be acknowledged, including the small number of patients and the short follow-up period. **Keywords:** COVID-19, SARS-CoV-2, CLINICAL CHARACTERISTICS, BIOLOGICAL FEATURES, PANDEMIC, RESPIRATORY ILLNESS.

COVID-19, caused by the coronavirus SARS-CoV-2, has emerged as one of the most devastating pandemics in modern history, profoundly impacting the lives and health of the global population. This respiratory disease was first identified in December

2019 in the city of Wuhan, Hubei Province, China, and quickly evolved to spread worldwide, becoming a major public health threat. The onset of the COVID-19 pandemic was characterized by a rapid spread of new cases, accompanied by increasing concerns among scientific communities, governments, and international health organizations. The SARS-CoV-2 virus has demonstrated an exceptional capacity for human-to-human transmission through respiratory droplets and direct contact, fueling its rapid dissemination across diverse social and geographic settings (1).

The stage of the COVID-19 pandemic continues to be dynamic and to evolve constantly. Despite substantial efforts to control the virus spread and develop vaccines and treatments, the adaptability of SARS-CoV-2 and the emergence of new strains have posed significant challenges for effective pandemic management.

In this article, we aim to analyze the progress of the COVID-19 pandemic, highlighting essential aspects of epidemiology, clinical and biological characteristics, as well as efforts to fight the disease and enhance medical responses. Understanding the evolution of the pandemic and the factors contributing to the success or failure of control measures is crucial for developing future strategies and improving global capacity for potential future pandemic threats.

Thus, this article seeks to provide a comprehensive overview of the COVID-19 pandemic evolution, with the purpose of making relevant contributions to the current management of the situation and identifying potential directions for action in the near future.

MATERIALS AND METHODS

We conducted a retrospective study that included 200 patients with clinically and radiologically diagnosed COVID-19, admitted to the Medical Clinic V of C.F. Iasi Clinical Hospital, Iasi, Romania, between 1st April and 29th June, 2020. The inclusion criteria were patients with confirmed diagnosis of COVID-19 who signed the informed consent. Patients with severe COVID-19 we excluded. All patients signed informed consent for study inclusion, and there were no age-related restrictions.

The study group was divided into two subgroups based on the presence of symptoms: I - 67 asymptomatic COVID-19 patients (33.5%), II - 133 symptomatic COVID-19 patients (66.5%). Complete clinical examination (medical history + objective clinical examination) was performed on admitted subjects; blood samples were collected for serological and biochemical tests, and imaging investigations (chest X-ray, computer tomography examination) were performed.

For statistical analysis, SPSS version 18.0 was used. Tests such as ANOVA were used to analyze the dispersion of the dependent variable, both intra and intergroup; the coefficient of variation (CV%) highlighted the percentage deviation between two means, providing results on the homogeneity of the value series. To calculate the significant difference between two or more groups, depending on the distribution of the value series, at a significance level of 95%, the following tests were applied for quantitative variables: the t-Student test - a parametric test that compares mean values recorded in 2 groups with normal distributions, and the F-test (ANOVA) used when comparing 3 or more groups with normal distributions. The chi-square test (c2) is a non-parametric test that compares 2 or more frequency distributions from the same population, applied when the

expected events are excluded. Sometimes, when a frequency in the calculation formula is small, Yates correction is applied to obtain a higher estimate of the difference. The Kruskall-Wallis correlation compares ordinal variables from 3 or more groups, while the Pearson correlation coefficient (r) represents the correlation between two variables from the same group (direct/indirect correlation). The ROC curve establishes the sensitivity/specificity balance of one parameter in relation to another.

RESULTS

Gender distribution showed a higher proportion of female patients, with a ratio of 2:1. Age ranged from a few days to 86 years, with a mean age of 44.34 years ± 15.88, and a median of 45 years. The majority of cases were found in the age group of 40-49 years (36.5%), both in females and males (40.6% *vs.* 28.4%; p=0.113). Regarding gender, it was observed that 38.6% of males and 44.4% of females were asymptomatic (p=0.452) (fig. 1).

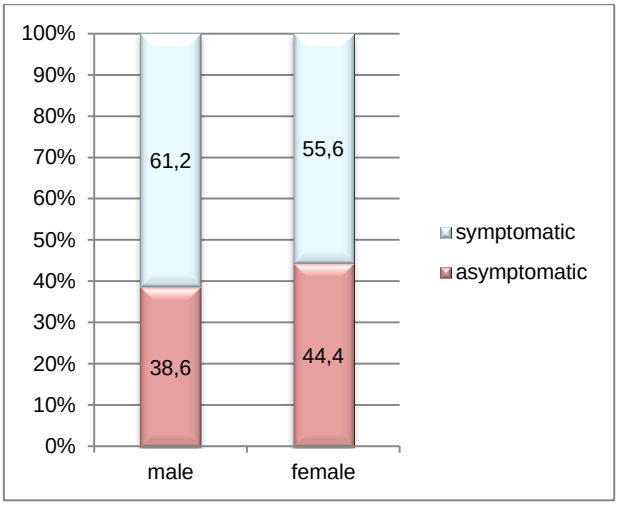

Fig. 1. Distribution of asymptomatic cases by gender

The proportion of asymptomatic cases by age groups revealed the following aspects (p=0.002) (fig. 2):

- In the age group under 10 years, 63.6% of children were asymptomatic.
- All children in the 10-19 age group were asymptomatic.
- Among adults, the highest proportion of asymptomatic cases was recorded in the 20-29 years group (58.3%) and 40-49 years group (49.3%).
- 77.8% of cases were asymptomatic in the 70-79 years age group.
- All elderly individuals in the over 80 years age group were symptomatic.

Upon admission, the estimated risk of SARS-CoV-2 infection was over 5 times higher in asymptomatic afebrile patients (RR=5.82; 95% CI: 0.88-38.65; p=0.004). Interestingly, if an afebrile patient presents with a cough, this symptom seemingly acts as a protective factor (RR=0.12; 95% CI: 0.02-0.84; p=0.001). Among symptomatic

patients, the presence of cough (RR=1.75; 95% CI: 1.47-2.09; p=0.001), anosmia (RR=1.80; 95% CI: 1.59-2.05; p=0.001), dyspnea (RR=1.78; 95% CI: 1.57-2.02; p=0.009), headache (RR=1.84; 95% CI: 1.59-2.06; p=0.001), and abdominal or chest pain (RR=1.77; 95% CI: 1.57-2.01; p=0.018) was associated with an approximately 2-fold higher risk of SARS-CoV-2 infection (tab. I).

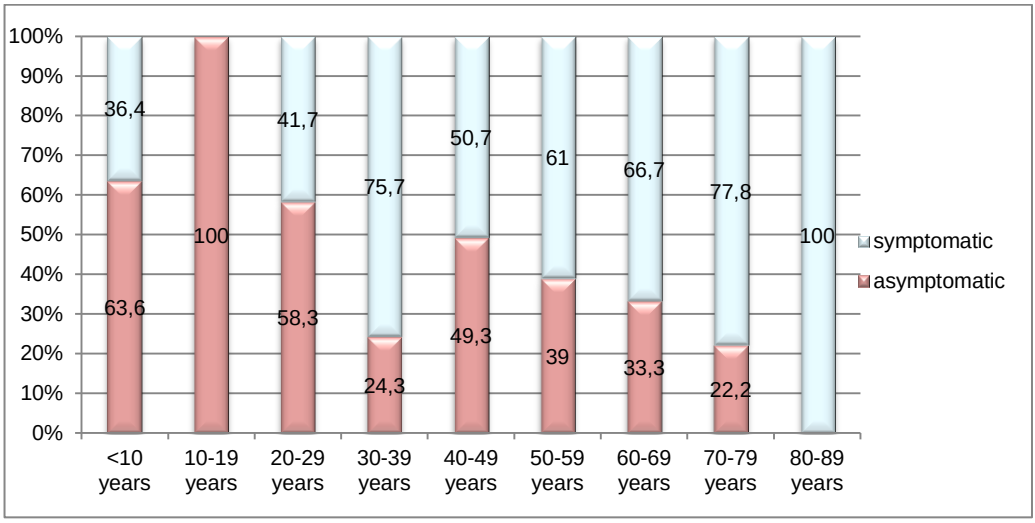

Fig. 2. Distribution of asymptomatic cases by age groups

TABLE I.

Estimated Risk of SARS-CoV-2 in Asymptomatic/Symptomatic Patients

Symptoms	Asymptomatic (n=85)	Symptomatic (n=115)	p-value
Afebrile	84 (98.8%)	103 (89.6%)	0.004
Cough	1 (1.2%)	17 (14.8%)	0.001
Anosmia	0 (0.0%)	9 (7.8%)	0.001
Dyspnea	0 (0.0%)	6 (5.2%)	0.009
Fatigue	1 (1.2%)	6 (5.2%)	0.101
Headache	0 (0.0%)	10 (8.7%)	0.001
Nausea	1 (1.2%)	2 (1.7%)	0.743
Pain	0 (0.0%)	5 (4.3%)	0.018

Note: RR - Relative Risk, IC95% - 95% Confidence Interval

Among comorbidities, in asymptomatic patients, only myocardial infarction induces an estimated risk of COVID-19 that is approximately 2 times higher (RR=1.74; 95% CI: 10.35-8.64; p=0.364) (tab. II).

Regarding biological parameters, in asymptomatic patients, CRP ranged from 0.58 to 39.88 mg/dL, while in symptomatic patients, the range was 0.20-200.17 mg/dL. The mean level was significantly higher in symptomatic patients (13.67 *vs.* 5.73 mg/dL; p=0.001).

TABLE II.
Estimated Risk of COVID-19 in Patients with Personal Pathological History (Comorbidities)

Comorbidities	Asymptomatic (n=85)	Symptomatic (n=115)	p-value
Type 2 Diabetes	5 (5.9%)	7 (6.1%)	0.952
Hypertension	15 (17.6%)	22 (19.1%)	0.789
Asthma	1 (1.2%)	1 (0.9%)	0.830
Chronic Hepatitis	1 (1.2%)	7 (6.1%)	0.059
Obesity	4 (4.7%)	7 (6.1%)	0.670
COPD	0 (0.0%)	2 (1.7%)	0.135
Thyroid Disorder	3 (3.5%)	4 (3.5%)	0.984
Autoimmune Disease	0 (0.0%)	2 (1.7%)	0.135
Myocardial Infarction	2 (2.4%)	1 (0.9%)	0.396

Note: RR - Relative Risk, IC95% - 95% Confidence Interval.

The mean level of white blood cell count did not differ significantly based on asymptomatic versus symptomatic status (6.45 *vs.* 6.61 thousand/mL^3; p=0.731) (tab. III).

The mean values of blood glucose (121.47 *vs.* 107.83 mg/dL; p=0.136), Alanine Aminotransferase-ALAT (49.98 *vs.* 54.40 U/L; p=0.445), and Aspartate Aminotransferase-ASAT (36.92 *vs.* 35.18 U/L; p=0.675) did not differ significantly between the analyzed groups (tab. III).

TABLE III.
Biological Parameters

Parameter	Asymptomatic	Symptomatic	-Student Tes
CRP, mg/dL	5.73±1.05 (0.58-39.88)	13.67±3.72 (0.20-200.17)	**0.001**
White Blood Cells (thousand/mL^3)	6.45±1.71 (3.14-12.05)	6.61±2.85 (2.62-25.86)	0.731
Blood Glucose, mg/dL	121.47±51.93 (79-316)	107.83±36.90 (60-310)	0.136
ALAT, U/L	48.98±32.86 (15-160)	54.40±39.96 (10-219)	0.445
ASAT, U/L	36.92±27.35 (16-181)	35.18±15.54 (10-86)	0.675

CRP-Protein C-reactive, ALAT-Alanine Aminotransferase, ASAT-Aspartate Aminotransferase

For imaging diagnosis, computed tomography (CT) scan was performed in 42.4% of asymptomatic patients and in 41.2% of symptomatic patients (p=0.874) (fig. 3).

Out of the total radiological investigation, 38.6% had a normal appearance (tab. IV).

The treatment for patients with COVID-19 was as follows: among asymptomatic patients, 37.6% received lopinavir/ritonavir and 15.3% received hydroxychloroquine, while symptomatic patients were treated with lopinavir/ritonavir in 57.4% of cases (p=0.006) and with hydroxychloroquine in 27.8% of cases (p=0.033) (fig. 4).

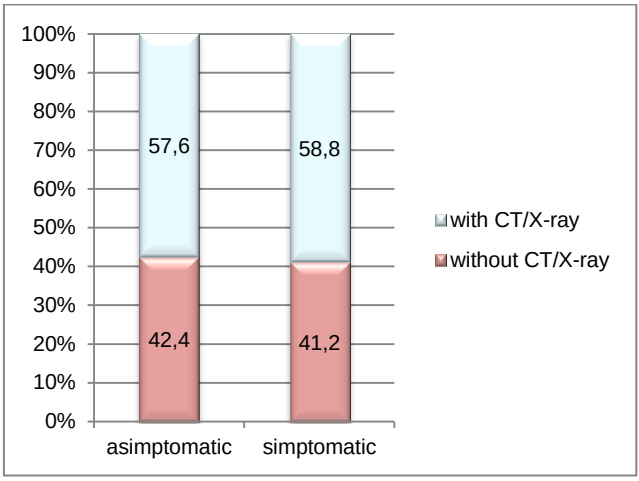

Fig. 3. Distribution of asymptomatic cases with imaging diagnosis

TABLE IV.
CT/X-ray

	n	%
Normal aspect	32	38.6%
Ground- glass opacity	23	27.7%
Multifocal nodular areas	11	13.3%
Large opacity	9	10.8%
Moderate opacity	3	3.6%
Small areas of alveolar condensation	4	4.8%
Pulmonary lesions	1	1.2%

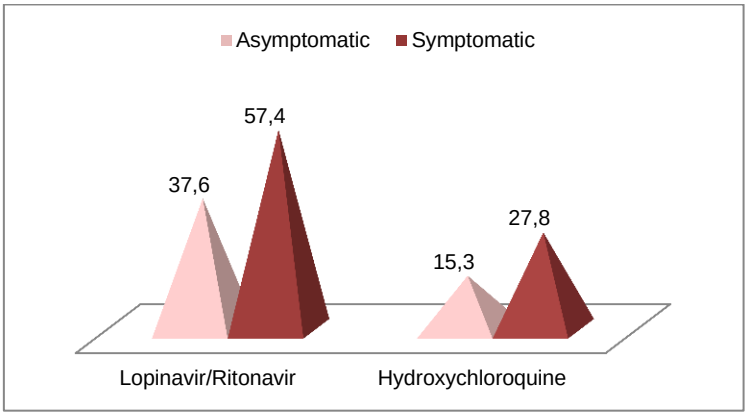

Fig. 4. Distribution of symptomatic/asymptomatic COVID-19 cases based on the received treatment

The number of days until negativity varied from 9 to 41 days in asymptomatic patients and from 2 to 38 days in symptomatic patients, with a similar average level in both study groups (18.71 *vs.* 18.79 days; p=0.936).

DISCUSSION

Identification of patients with COVID-19 is challenging, and risk monitoring strategies for disease progression are limited. Previous studies have reported that SARS-CoV-2 has been isolated from asymptomatic individuals, and a significant percentage of the infections have been transmitted by asymptomatic patients (2, 3, 4). Thus, the high proportion of asymptomatic subjects in our study (1/3 asymptomatic subjects, 38.6% of men, and 44.4% of women) supports the importance of social distancing for controlling the pandemic. In this study, approximately 1/2 of children under 20 years old were asymptomatic. Among adults, the highest proportion of asymptomatic cases was recorded in the 20-29 years and 40-49 years age groups (49.3%), and 2/3 of individuals over 70 years were asymptomatic.

In the current research, the most prevalent symptom, accounting for approximately 15% of cases, was cough, followed by anosmia and headache. A study including 13 subjects with mild COVID-19 reported nasal congestion (62%) as the main symptom (5). Interestingly, hyposmia was quite commonly encountered in subjects with mild COVID-19. Although hyposmia is caused by post-viral olfactory dysfunction (6), further studies are needed to determine the specificity of this symptom in COVID-19. Moreover, future pathophysiological studies are necessary to evaluate whether this unique symptom is associated with nasal congestion, olfactory nerve dysfunction due to viral infection, or other comorbidities. In our study, anosmia was present in 7.8% of symptomatic patients and represented one of the main subjective complaints declared by the patients.

Previous studies show that 50% of COVID-19 patients develop dyspnea after approximately 8 days after the onset of symptoms (7). Dyspnea was present in 5.2% of the current research, involving five subjects.

Previous studies suggest that advanced age, male gender, and the presence of comorbidities may represent risk factors for disease progression and a reserved prognosis (8). In another recent epidemiological study conducted in China, it was reported that patients with pre-existing comorbidities accounted for 23.2% of mild cases and 37.6% of severe cases (9). Other observational studies evaluating the characteristics of COVID-19 patients have shown similar results (1, 10), indicating that the presence of comorbidities is associated with disease severity. In our study, it was demonstrated that myocardial infarction induces an estimated risk of SARS-CoV-2 infection that is approximately 2 times higher. In the present study, 17.6% of patients had a personal history of hypertension.

As reported in one study, some biomarkers differ significantly among patients based on the severity of the disease (9). Another study indicates that the percentage of leukocytes predicts the outcome of individuals with COVID-19 (10). In our study, leukocytosis was more commonly found in symptomatic patients.

It is also reported that elevated D-dimer concentration, lymphopenia, and an in-

creased neutrophil-to-lymphocyte ratio are frequently encountered in patients with severe COVID-19 compared to those with mild forms of the disease (11). Lymphopenia, which is a common feature of symptomatic COVID-19 (12), may be a direct consequence of SARS-CoV-2 infection or mediated by inflammatory cytokines.

Similarly, in our study, although the mean levels of CRP exceeded the reference value in both analyzed groups, it was more severe in symptomatic COVID-19 patients.

Other studies (13, 14) report that pathological lung changes range from ground-glass opacities to consolidation during the course of the disease, and the appearance of consolidative features was more frequent at 1-3 weeks after the onset of the first symptom.

The occurrence of pulmonary consolidative features is associated with a deterioration of the patient general condition. Various types of pulmonary changes were observed in both symptomatic and asymptomatic subjects. Previous reports on imaging in COVID-19 also mention changes in asymptomatic individuals (15). In the present study, approximately 40% of the subjects underwent imaging explorations, but in one-third of them, the results were normal.

One-third of asymptomatic patients were treated with lopinavir/ritonavir, and approximately 15% with hydroxychloroquine. The number of days until negative conversion was around 19±7 days.

CONCLUSIONS

Our article provides valuable insights into the multifaceted nature of the pandemic. It sheds light on the significant proportion of asymptomatic cases, highlighting the need for social distancing measures to control transmission. Age and pre-existing health conditions were identified as risk factors for severe outcomes, emphasizing the importance of protecting vulnerable populations.

Symptoms of COVID-19 varied, with cough, anosmia, and headaches being some of the common manifestations. The understanding of anosmia, even in mild cases, sparked further interest for future research.

Laboratory tests, such as CRP levels and leucocyte counts, proved essential in predicting disease progression and guiding medical interventions. Additionally, imaging played a critical role in monitoring lung changes and the extent of lung involvement. Treatment strategies, were explored to manage asymptomatic cases, but ongoing research is needed to assess their effectiveness fully.

Throughout this challenging journey, the importance of vaccination emerged as a beacon of hope, offering a way to build immunity and control the spread of the virus. The pandemic has taught humanity valuable lessons about global collaboration, scientific advancements, and the significance of adhering to public health measures. It serves as a reminder that the fight against COVID-19 is ongoing, but with continued resilience and unity, the world can overcome this unprecedented crisis.

As we move forward, it is imperative to maintain a vigilant approach, embrace scientific evidence, and foster international cooperation to safeguard public health and ensure a healthier and safer future for all.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest and they received no funding.

COVID-19 NEUROLOGICAL MANIFESTATIONS - THE EXPERIENCE OF A TERTIARY HOSPITAL FROM NORTHEASTERN ROMANIA (Abstract): Well-known for its respiratory tropism, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), can further affect both the central and peripheral nervous system causing a substantial source of morbidity and mortality. This study aimed to evaluate the neurological manifestations in SARS-CoV2-infected hospitalized patients and to evaluate the short-term outcomes based on clinical features, neurologic comorbidities, and laboratory. **Materials and methods**: We retrospectively analyzed medical records of patients with SARS-CoV-2 infection admitted to the "Sf. Parascheva" Clinical Hospital of Infectious Diseases Iasi between May 2020 and December 2022. Clinical features, frequency of neurological manifestations, and correlation with risk factors, pandemic waves, and the severity of the disease were evaluated. **Results**: We identified 160 patients hospitalized during the investigated period, the most frequent neurologic manifestations at the time of admission were fatigability (85% cases), headache (51.25% cases), myalgia (41.25% cases), vertigo (26.88% cases), confusion (21.25% cases) and less frequent anosmia (16.88% cases), ageusia (15% cases), paresthesia (3.13% cases). In all phases fatigability was predominant, being in over 80% of cases one of the symptoms at the moment of hospitalization, followed by cephalalgia and myalgia. Anosmia (25%) and ageusia (27%) were found most in phase two compared to all phases. In the second phase, the variant of concern was delta, causing more critical cases than all the other mentioned periods. Previous neurologic comorbidities such as dementia and stroke were correlated with a higher mortality risk. **Conclusions**: Neurological symptoms were a relatively frequent part of the clinical picture of SARS-CoV2 infection, and their incidence varied in different pandemic waves. Fatigability was the most constant finding. Previous neurologic comorbidities such as dementia and stroke were correlated with a higher mortality risk. **Keywords**: NEUROLOGICAL, CORONAVIRUS, SARS-COV-2, FATIGUE.

The coronavirus disease 2019 (COVID-19) was the most challenging public health issue in decades and was caused by the severe acute respiratory syndrome corona-

virus 2 (SARS-CoV-2). Known for its respiratory tropism, the virus can further affect both central and peripheral nervous systems causing a substantial source of morbidity and mortality.

The central nervous system manifestations are headache, encephalitis, and encephalopathy; the peripheral nervous system involvement can be expressed as anosmia and ageusia and skeletal muscle manifestations, such as myalgia and myasthenia (1). The underlying mechanisms of neurologic complications in patients with COVID-19 are di-verse and multifactorial. One of them is represented by systemic dysfunction; patients with severe illness admitted for respiratory failure can develop encephalopathy or other neurological manifestations due to hypoxemia and metabolic imbalances. The immune dysfunction induced by the virus due to a proinflammatory state and autoimmunity also plays an important role in the pathogenesis of acute neurological symptoms. Patients with COVID-19 can develop signs of severe systemic inflammation consistent with a cytokine release syndrome-like presentation shown as elevated inflammatory markers (D-dimer and ferritin) and proinflammatory cytokines (IL-6 and TNF-alpha) (2). High levels of circulating proinflammatory cytokines can cause confusion and alteration of consciousness (3). SARS-CoV-2 enters the cells using a membrane-bound protein called angiotensin-converting enzyme 2 (ACE-2). ACE-2 has a wide distribution in multiple organs including the nose, lungs, kidneys, liver, blood vessels, immune system, and the brain; its physiological effect is to regulate blood pressure and to facilitate the conversion of angiotensin II to angiotensin 1-7 (4, 5). When SARS-CoV-2 binds to ACE2, the levels of angiotensin II rise causing damage to the endothelial cells therefore promoting vasoconstriction, kidney failure, heart disease, apoptosis, and oxidative processes that accelerate aging and boost brain degeneration (6,7). Direct viral invasion of the nervous system is another possible culprit mechanism (8).

Multiple variants of SARS-CoV-2 have emerged during the pandemic, including Alpha, Gamma, Zeta, Delta, Lambda, and Omicron, each with its subtypes presenting different patterns of transmission and immunology and different levels of severity. With the evolution of the virus and the increasing immune protection of the population (following vaccination or natural infection), the clinical picture of COVID-19 is also changing, with the frequency and intensity of some symptoms (including neurologic ones) being different in the present. COVID-19 effects on the body, including the neurological impact vary due to viral strain, host, and environmental conditions.

We conducted a retrospective study to determine the incidence of neurological symptoms during an acute COVID-19 episode and the way they varied during the waves of the COVID-19 pandemic and to identify how different neuro-psychiatric disorders may influence the short-term outcome of COVID-19 infection in hospitalized patients from our geographical region.

MATERIALS AND METHODS

Retrospective study of patients diagnosed with SARS-CoV-2 infection, admitted at the “Sf. Parascheva” Hospital of Infectious Diseases Iasi between May 2020 and December 2022. The diagnosis was confirmed by real-time reverse transcrip-

tion-polymerase chain reaction (RT-PCR) assay from nasopharyngeal swab samples.

The study period was stratified based on the RT PCR SARS-CoV-2 positive test month to identify temporal trends in cases. Population data were divided into four phases (fig. 1):

- Phase 1: May 2020-February 2021 (first three waves)
- Phase 2: August-December 2021 (fourth wave)
- Phase 3: January-May 2022 (fifth wave)
- Phase 4: June 2022- December 2022 (sixth wave)

The variants of concern in the studied periods are as follows: in phase one the dominant strain was Alpha (lineage: B.1.1.7, Q), followed by Delta (lineage: B.1.617.2, AY.4.2) in phase two and Omicron (lineage: B.1.1.529, BA) during phase three and four.

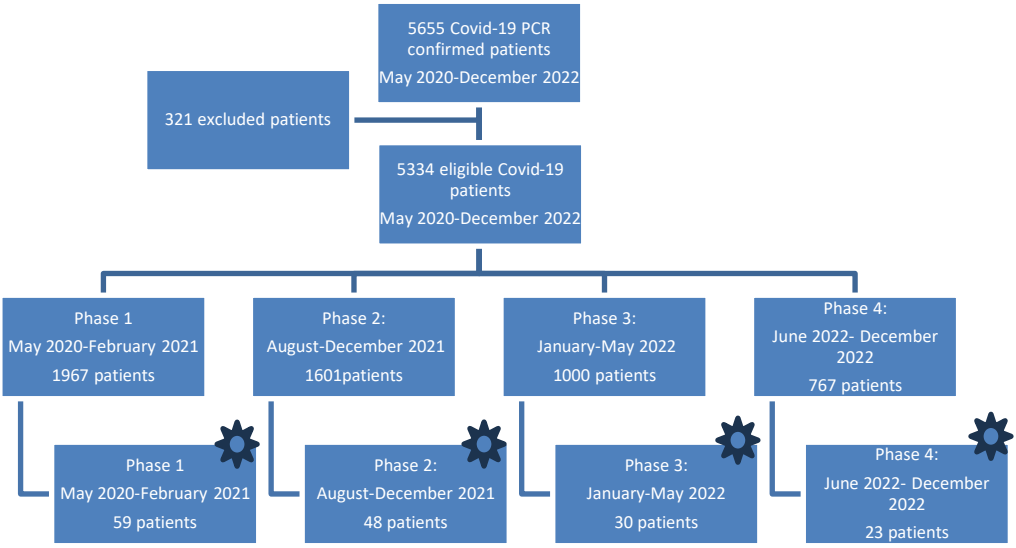

Fig. 1. Study population flow-chart. -3% sample extraction following simple randomization

All hospitalized COVID-19 patients were included in an anonymous database. Patients in a comatose state at admission who required immediate admission to the intensive care unit, the ones with acute psychiatric conditions, and those who were unable to offer data regarding their symptoms and history were excluded. 3% of admitted patients in each one of the studied phases were selected using simple randomization through a randomization software (Power Analysis & Sample Size - PASS© 2023).

A total of 160 cases were obtained.

The neurological symptoms considered were represented by: fatigue, headache, anosmia, ageusia, vertigo, paresthesia, confusion, and myalgia.

We reviewed electronic files, collecting paraclinical and clinical data including demographic data, medical history, the onset and the severity of symptoms at admission, and the outcome.

The severity of the illness was graded according to National Institute of Health

US COVID-19 guidelines as follows: mild illness: various signs and symptoms of COVID-19, but without shortness of breath, dyspnea, or abnormal chest imaging; moderate illness: evidence of lower respiratory disease during clinical assessment or imaging and oxygen saturation measured by pulse oximetry (SpO2) ≥94% on room air; severe illness: individuals who have SpO2 <94% on room air at sea level, PaO2/FiO2 <300 mm Hg, a respiratory rate >30 breaths/min, or lung infiltrates >50%; critical illness: individuals who have respiratory failure, septic shock, and multiple organ dysfunction.

Encephalopathy was defined as a disturbance in the level of awareness and attention, leading to an alteration in cognitive function, not primarily due to structural organic brain disease.

We monitored the predictors of short-term outcomes of the patients dividing them into four separate groups. The first two groups were divided by the severity of the illness including critical patients who needed ICU care due to acute respiratory failure and multiple organ dysfunction and patients who maintained a moderate/severe form of illness without needing ICU support. The two other groups were divided by the lethality rate, one included the patients who survived, and the other one the ones who died due to COVID-19 infection.

Statistical analysis was performed using XLSTAT software version 2022. Descriptive data are presented as absolute values, percentages, and means. Differences between groups were tested for statistical significance using unpaired T-Student and χ square tests. $p < 0.05$ was considered to indicate a statistically significant difference.

RESULTS

There were 83 women and 77 men, aged 27-94 (median: 67, interquartile range (IQR) 56-75). The interval from the onset of symptoms and hospital admission was 6 days median, with an interquartile range IQR 4-7. Other patient characteristics are summarized in first table.

TABLE I.
Patient characteristics

	Critical N=28		Moderate and severe N=132		Survivors N=145		Deceased N=15	
	Median	IQR	Median	IQR	Median	IQR	Median	IQR
Age at COVID-19 onset	71	66.2-77	66	55.2-75	67	56-75	71	67-78
Days since symptoms onset	7	4.2-7	6	3-8	6	3-6	7	4-7
Hospitalization days	14.5	6.7-22.2	12	9-16	12	9-16	12	9-16

None of the selected patients presented a mild form of disease. From the total number of patients, 48.12% had a moderate illness, 34.37% had a severe illness and 17.5% had a critical form of the infection. Phase 2 contained the highest proportion of severe and critical cases, the difference from the other phases being significant (p=0.004). (tab. II).

In the group of patients who were stable with moderate/severe forms of illness and improved by the time of discharge the me-

dian age was 66 years and IQR 55.25-75, more women were included (54.55%) from urban areas; the most frequent associated comorbidities were cardiovascular diseases (68.18%) such as hypertension, cardiomyopathies and heart failure.

TABLE II.
Number of cases and illness severity in different phases

	Phase 1		Phase 2		Phase 3		Phase 4	
No cases	59		48		30		23	
	n	%	n	%	n	%	n	%
moderate	36	46.7	11	14.2	16	20.7	14	18.1
severe	17	30.9	23	41.8	9	16.3	6	10.9
critical	6	21.4	14	50	5	17.8	3	10.7

In the group of critical patients, the median age was 71 years and IQR was 66.2-77, the patients being older in this group; 60.71% were male, 96.43% had comorbidities, over 60% had associated cardiovascular disease, 28.57% had previous neurological illnesses such as stroke (including intracerebral hemorrhage, ischemic stroke and transient ischemic attack), dementia, neuromuscular disorder, motor neuron disease, spinal cord disorder, the last three ones being less frequent. In this group, the hospitalization period was longer compared to the other ones, with a median of 14.5 days and IQR 6.75-22.25.

The most frequent neurologic manifestations were fatigability (85% cases), headache (51.25% cases), myalgia (41.25% cases), vertigo (26.88% cases), confusion (21.25% cases) and less frequent anosmia (16.88% cases), ageusia (15% cases), paresthesia (3.13% cases) (fig. 2)

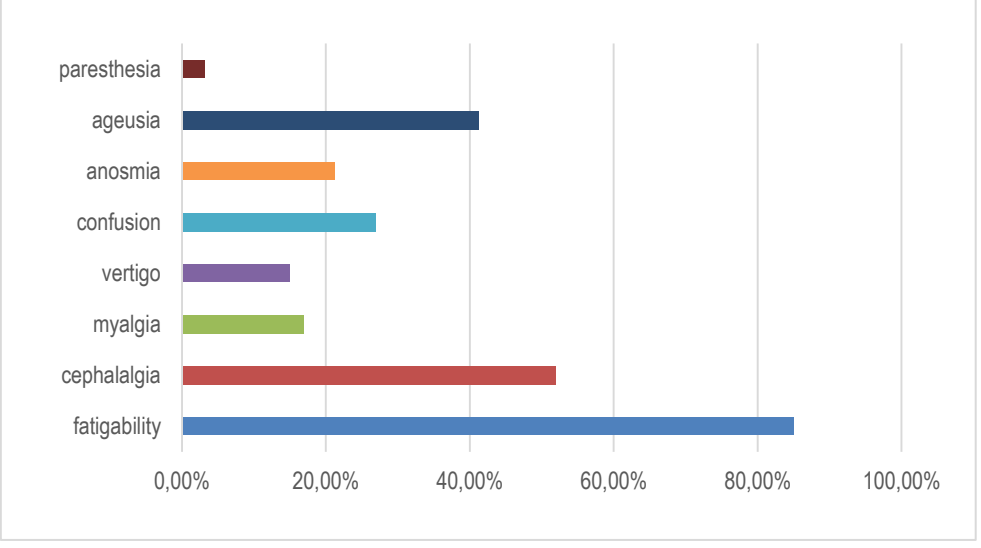

Fig. 1. Neurological symptoms

In all phases, fatigability was predominant, being in over 80% of cases one of the symptoms at the moment of hospitalization, followed by cephalalgia and myalgia. Anosmia (25%) and ageusia (27%) were found most in phase 2 compared to all phases.

TABLE III.
Frequency of neurological manifestation in different phases of the pandemic

	Phase 1	Phase 2	Phase 3	Phase 4	p
	(n=59)	(n=48)	(n=30)	(n=23)	
	%	%	%	%	
Fatigability	81.36%	83.33%	93.33%	86.96%	0.49
Cephalalgia	42.37%	43.75%	76.67%	60.87%	**0.009**
Anosmia	11.86%	25.00%	13.33%	17.39%	0.31
Ageusia	8.47%	27.08%	10.00%	13.04%	**0.04**
Vertigo	15.25%	31.25%	30.00%	43.48%	**0.048**
Confusion	23.73%	20.83%	23.33%	13.04%	0.74
Myalgia	32.20%	52.08%	50.00%	30.43%	**0.09**
Paresthesia	0.00%	4.17%	0.00%	13.04%	**0.01**

The temporal trend in the described periods showed that fatigue was constant in all phases, headache was more frequent during phases 3 and 4, ageusia during phase 2, vertigo in phase 4, myalgia in phases 2 and 3, and paresthesia in phase 4 (tab. III).

During the hospitalization, 12 patients (7.5%) developed encephalopathy. The incidence has sub sequentially decreased during the studied periods, with a peak in the first two phases (9/12 patients). The median age and hospitalization duration were significantly higher in this group (73 *vs.* 67 years, p=0.04 and 16 *vs.* 12 days, p=0.03). Nine of the 12 encephalopathy patients had a lumbar puncture performed, but none showed an inflammatory reaction in the cerebrospinal fluid (CSF). A borderline elevation of the CSF albumin was detected in 3 patients. No other specific investigations for the diagnosis of a possible acute inflammatory demyelinating polyneuropathy were performed.

In all, 15 patients died in the hospital. Compared to those discharged alive, patients who died were older (the median age at COVID-19 onset 71 years, IQR 67-78), predominantly male (73.3%) from urban areas, with more comorbidities (cardiovascular disease including hypertension, diabetes type 2, obesity. 46.76% had previously neurological diseases such as stroke (p=0.0023) and dementia (p=<0.001), both being correlated with death. Almost all deceased people were admitted to the ICU (80%), and all of the ICU patients required mechanical ventilation (tab. IV). Between the alive and dead groups, there's no difference between the hospitalization days.

The days from the onset of COVID-19 symptoms to hospital admission are similar

in all groups, with a median of 7 in the critical and dead groups and a median of 6 in the stable/improved outcome and alive groups.

In what concerns the laboratory parameters used to regularly monitor the patients, we found a significant statistical correlation ($p < 0.05$) between anemia (hemoglobin <11.7 g/dL in females and <13.2 g/dL in males) p=0.005, neutrophilia (>8*10³/μL) p<0.0001, lymphocytopenia (lymphocytes < 1*10³/μL) p<0.0001, thrombocytopenia (<150,000/mm³) p<0.0001, high levels of D-dimer (>0.5mg/L FEU) p<0.0001, high levels of ferritin (>400ng/mL) p<0.0001 and both worse outcome and mortality risk. From this group 64.29% had anemia, 85.71% had lymphocytopenia, 53.57% had neutrophilia, 53.57% had thrombocytopenia, 67.86% had high levels of D-dimer and 60.71% had high levels of ferritin. The significant statistical correlation persists in the deceased group, between anemia (73.33%) p=0.00132, neutrophilia (66.67%) p<0.0001, lymphocytopenia (86.67%) p<0.0001, thrombocytopenia (53.33%) p<0.0001, high levels of D-dimer (93.33%) p<0.0001, high levels of ferritin (66.67%) p<0.0001 and death.

The C reactive protein levels were high in all groups, but in the deceased patient's group, it was high in 100% of the cases.

Others	2	7.14%	7	5.30%	0.641	8	5.52%	1	6.67%	0.803

Concerning laboratory investigations, independent predictors for an increased risk of mortality were: anemia (p=0.001, OR 5.2, 95% CI 1.58-17.25), neutrophilia (p<0.0001, OR 10.61, 95% CI 3.31-33.91), lymphocytopenia (p<0.0001, OR 5.58, 95% CI 1.21-25.6), thrombocytopenia (p<0.0001, OR 4.03, 95% CI 1.36-11.97), high D-dimer levels (p<0.0001, OR 25.8, 95% CI 3.29-201.8) and high ferritin levels (p<0.0001, OR 4.44, 95% CI 1.43-13.7) (tab. VI).

TABLE VI.
Significant predictors for increased mortality

Predictors	P value	Odds ratio (OR)	95% confidence interval (95% CI)
Stroke	0.0023	4.43	1.20-16.23
Dementia	<0.001	7.28	1.11-47.59
Anemia	0.00132	5.22	1.58-17.25
Neutrophilia	<0.0001	10.61	3.31-33.91
Lymphocytopenia	<0.0001	5.58	1.21-25.6
Thrombocytopenia	<0.0001	4.03	1.36-11.97
High D-dimer	<0.0001	25.80	3.29-201.8
High ferritin	<0.0001	4.44	1.43-13.7

DISCUSSION

This study aimed to identify the incidence of neurological symptoms during the acute COVID-19 infection and the way they varied in different periods of the pandemic, in hospitalized patients from northeastern Romania. It was found that the most common neurological symptom is fatigue followed by headaches. The temporal trend in the described periods showed that fatigue was constant in all phases, headache was more frequent during phases 3 and 4, ageusia during phase 2, vertigo in phase 4, myalgia in phases 2 and 3, and paresthesia in phase 4. To mention, the study was conducted in a tertiary care hospital, in the infectious diseases department. The patients who needed acute neurological care were directed to another hospital. A study from India (9) compared the first two waves of the pandemic in the matter of neurological manifestations, identifying headaches and fatigability as the most frequent symptoms in both waves, similar to our findings.

The neurological symptoms of COVID-19 infection are known to be more common in patients with severe illness (10), and none of our patients who showed neurological symptoms during hospitalization had a mild form of disease.

Every virus can mutate, more often with no significant effect on its pathogenic properties, however, during the major pandemic waves, some mutations result in new strains with higher transmission rates, like the SARS-CoV-2 Delta strain, which has been associated with higher viral loads, enhanced transmissibility, and higher hospitalization rates (11). A study conducted during a period of co-circulation of Omicron and Delta concluded that the Omicron variant appears to cause significantly less severe disease compared to Delta (12). In our study, the most critical cases of SARS-CoV-2 infection were found during the period when Delta was the main variant of concern.

Systemic reviews of the literature identified headache, fatigability, and dizziness/myalgia as the most constant neurological symptoms in COVID-19 patients (13-16). These symptoms are not highly specific to COVID-19 and don't presuppose necessarily an infection to underlying neurological structures, but they could also occur via indirect mechanisms of neuropathogenicity (dehydration, fever, hypoxia, or respiratory distress) as well influenced by the proinflammatory state (16). The neurotropism of the SARS-CoV-2 virus has been debated during the pandemic, in 2020 Moriguchi *et al.* and Poyiadji *et al.* described the first case of encephalitis with the detection of SARS-CoV-2 RNA in cerebrospinal fluid (CSF), but in other encephalitis case reports published, viral RNA was not detected in CSF or complementary investigations were not performed (17). An autopsy study from 2022, of 20 brains of decedents with acute COVID-19 infection, hasn't detected viral RNA or viral proteins in the CSF or brains, the acute changes found in the study have mostly a vascular origin with acute hypoxia, infarcts, and hemorrhages and inflammatory reactions (18).

Headache has been described as a frequent non-specific neurological symptom in a series of studies (19). It is experienced by 12-70% of patients with COVID-19 (20). In our study, 50% of the patients complained of this symptom. Different types of headaches have been reported such as tension-type headaches, headaches resulting from systemic viral infections that cause chronic cough or hypoxia, and migraine-type headache exacerbation (21).

Fatigability was the most common finding in our study, 85% of the patients complained about different grades of fatigability, and most of them described it as having "never felt so tired", but it is one of the most difficult symptoms to quantify because of its subjective nature, therefore is not always considered as an important finding. The pathology behind this symptom is diverse and cannot be explained by just one mechanism. Some promising factors include inflammation, mitochondrial dysfunction, sleep alterations, autonomic nervous system abnormalities, and poor nutritional status (22). This is one of the most persistent symptoms in long-covid, causing persistent tiredness, and effort-independent, which reduces the quality of life.

Taste and smell disorders were the most common, sudden neurologic symptoms of COVID-19 at the beginning of the pandemic, and are thus considered a useful early diagnostic marker (23). Anosmia and ageusia are more frequent in patients with mild illness who usually don't require hospitalization (24), therefore the lower incidence in our study: 16% for anosmia and 15% for ageusia. In one study, the incidence was over 80% (25), but in a meta-analysis with more than 27000 subjects included, anosmia affected 48% of patients (26). These symptoms are rarely the only COVID-19 manifestations, are more common in younger people and females reported it more often (27). The prognosis of smell and taste disorders associated with COVID-19 is generally favorable and, in most cases, it resolves spontaneously (28).

Besides the common neurological symptoms, major and devastating SARS-CoV-2 virus-associated CNS complications can occur such as encephalopathy and encephalitis (27). Encephalopathy is a major neurological manifestation, with a multifactorial origin, including systemic disease and in-

flammation, coagulopathy, direct neuroinvasion by the virus, endothelytis, and possibly post-infectious auto-immune mechanisms (30). Additionally, other risk factors associated with intensive care units should be taken into account as sedation and analgesia doses, disruption of sleep/wake cycles, and infectious complications (31). Previous studies showed an increase in mortality and morbidity associated with encephalopathy, as well as an increase in the hospital length of stay, this finding being consistent with our data (29, 32).

We stratified the patients into two groups according to the outcome of the infection. In all, 15 patients died in the hospital. Compared to those discharged alive, patients with increased mortality were older, predominantly male from urban areas, with more comorbidities such as cardiovascular disease, including hypertension, and diabetes type 2 obesity. 46.76% had previously neurological diseases such as stroke and dementia, both being correlated with death. Almost all deceased people were admitted to the ICU, and all of the ICU patients required mechanical ventilation. In two other studies (33, 34) stroke and dementia were associated with increased disease severity.

Concerning laboratory investigations, independent predictors in our study for an increased risk of mortality were anemia, lymphocytopenia, thrombocytopenia, high D-dimer levels, and high ferritin levels. Azhideh (35) also noticed lower lymphocyte and platelet counts in patients with severe central nervous system (CNS) involvement, while laboratory findings were not helpful in patients with peripheric nervous system involvement or individuals with non-severe CNS involvement. Similar findings were reported by Trofin *et al*. (36).

Given the global impact of COVID-19 and the emerging recognition of its neurological effects, this research adds to the body of knowledge required for comprehensive disease understanding and management.

It is now recognized that the clinical picture of COVID-19 has changed since the start of the pandemic, the most important drivers for these changes being the different virus variants involved and the immune response gained by a partially vaccinated or naturally immunized population (37, 38). Some authors also recognize some regional differences in the reported symptoms of COVID-19, due possibly to cultural or genetic differences (39,40). Our study, with its regional focus, provides specific insights that could be relevant for understanding the disease's manifestation in particular demographic and geographical settings.

Our study has several limitations, first of all, by its retrospective nature and by the small sample of analyzed patients, even though they were selected from various periods, matching with different waves of the pandemic and different variants of the virus. Most of the symptoms were self-reported and due to the retrospective nature of our study, we were unable to use more objective tools to quantify them. At this time, we were able to include only short-term outcomes at discharge. Long-term follow-up is needed to assess the outcomes more efficiently and to identify the persistent symptoms and the impact of neurological symptoms due to COVID-19 on daily life including possible sequelae.

CONCLUSIONS

Neurological symptoms were a relatively frequent part of the clinical picture of SARS-CoV2 infection, and their incidence

varied in different pandemic waves. Fatigability was the most constant finding. Previous neurologic comorbidities such as dementia and stroke were correlated with a higher mortality risk. Other independent predictors for an increased risk of mortality are anemia, lymphocytopenia, thrombocytopenia, high levels of D-dimer, and high levels of ferritin.

ACKNOLEGDMENTS

CHRONIC VENOUS DISEASE AND PSORIASIS- JUST A RANDOM ASSOCIATION? (Abstract): **Aims:** Chronic venous disease and psoriasis are two common pathologies in dermatological practice. The aim of this study is to determine the prevalence of venous disease among the psoriatic population and to identify risk factors that lead to their association**.** **Materials and methods**: This study included 375 patients diagnosed with psoriasis vulgaris, hospitalized in "Sf. Spiridon" County Clinical Emergency Hospital's Dermatology-Venereology Clinic, between 01.01.2019 and 31.05.2021. **Results**: The prevalence of chronic venous disease in the study group was 37.3%, reaching the highest values in the age group of 36-60 years (women: 40.7%, men: 48.6%, $P = 0.040$). Among the common risk factors, obesity had a prevalence of 19.2% and smoking 24.3% ($P = <0.001$). Among common comorbidities, hypertension had a prevalence of 47.1% and diabetes mellitus 13.6% ($P = <0.001$). **Conclusions**: In the future, more studies are required, in order to fully elucidate the mechanisms by which venous disease can be associated with psoriasis. **Keywords**: PSORIASIS, CHRONIC VENOUS DISEASE, OBESITY, SMOKING.

INTRODUCTION

Psoriasis is a chronic inflammatory disease, with a global prevalence of 2-4% and a mild evolution in 2/3 of cases (1). The etiopathogenesis of psoriasis is not fully elucidated. Clinical manifestations of psoriasis vulgaris include the appearance of erythematous-scaly plaques, well delimited, with the surface covered by white, fine, easily removable scales (2, 3). Other clinical types are guttate, pustular, erythrodermic and inverse psoriasis. It usually affects young people, between the ages of 20 and 40 years (1). Internal or external risk factors cause immunologic and metabolic dysregulations, that can trigger the disease in genetically predisposed individuals (4, 5). The immune system responds with T cells hyperactivation and T-helper 1 cells upregulation

(6, 7).

Chronic venous disease (CVD) is a common vascular pathology, produced by disturbances in the return of blood in the deep, superficial and perforating venous systems. Increased venous pressure occurs most often by weakening of the vascular wall and secondary to valvular insufficiency. Venous hypertension causes extravasation of water and erythrocytes in the tissues, leading to skin lesions (8). Clinical manifestations of CVD include discomfort and pruritus of lower limbs and suggestive signs include the appearance of varicose veins, leg edema, purple lesions or lipodermatosclerosis, as well as ulcers (9).

Common risk factors involved in the etiopathogenesis of psoriasis and chronic venous disease are obesity and smoking. Obesity is a risk factor in the development of venous valvular insufficiency in CVD due to the mechanical component and the systemic proinflammatory status produced by adipose tissue, accentuated by sedentary lifestyle and impaired pumping function of the leg muscles (10). Obesity can also lead to psoriasis (11). Hypertension is considered a comorbidity of psoriasis but there are studies in which hypertensive patients have associated an increased incidence of psoriasis (12). Also, high blood pressure can be a factor in the onset or worsening of venous disease (13).

We performed a cross-sectional study, including 375 patients, aiming to determine the prevalence of CVD among the psoriasis population and to identify risk factors that lead to their association.

MATERIALS AND METHODS

We included in this study all patients diagnosed with psoriasis vulgaris (L40.0) between 01.01.2019 and 31.05.2021, resulting 375 patients, hospitalized in "Sf. Spiridon" County Clinical Emergency Hospital's Dermatology-Venereology Clinic. The characteristics of the patients admitted in the study were: age, sex, environment, primary diagnosis and secondary diagnoses, PASI and DLQI severity scores. All patients included in the study signed their consent to the processing of personal data.

The assessment of the severity of psoriasis was performed by the doctors, using the PASI score (Psoriasis Area and Severity Index) and the impact on the quality of life was quantified using the DLQI score (Dermatology Life Quality Index). The assessment of the severity of chronic venous disease was performed using the CEAP (Clinical Etiology Anatomy Pathophysiology) classification, as follows: C0-without signs of venous disease; C1-intradermal telangiectasias or subdermal reticular veins (diameter between 1-3mm); C2- varicose veins (diameter over 3 mm); C3-edema in the ankle or calf; C4-venous eczema, lipodermatosclerosis or white atrophy; C5-healed venous ulcer; C6- active venous stasis ulcer (14).

In determining the obesity class, we used the Body Mass Index (BMI), as follows: grade I-BMI obesity with values between 30 and 34.99; grade II-BMI obesity with values between 35 and 39.99 and grade III-BMI or morbid obesity with values of 40 or more (15).

The statistical analysis of the patients' data was performed using the SPSS program version 20.0 and the calculation of the chi-square test, as follows: p <0.05, the statistical value is moderately significant (S, 95% c); p <0.01, the statistical value is very significant (S, 99% confidence); p <0.001, the statistical value is highly significant (HS, 99.9% confidence); p> 0.05, the statistical value is not significant (NS).

RESULTS

The prevalence of chronic venous disease among the psoriatic patients was 37.3%, representing 140 patients out of a total of 375 patients included in the study.

From first table, we can observe that the prevalence of CVD in the psoriatic population has the highest values in the age category 36-60 years, both in females and males, with values of 40.7% and 48.6%, followed by the age category with patients over 60 years, with a percentage of 35.9% for females and 38.0% for males. The lowest prevalence was in the age category 18-35 years, with a value of 23.4% in women and 13.5% in men (P = 0.040).

In the group of psoriatic patients who also associated the diagnosis of CVD, there was a slight predominance of males (55%) (P = 0.055) and the mean age was 60.06 ± 12.35 years (P = 0.027). Regarding the local environment, 55.7% of patients belong to urban areas (P = 0.033) and 44.3% come from rural areas (P = 0.041).

From second table, we can observe that after the classification according to the clinical stage of the chronic venous disease, most of the patients were classified in CEAP C3 (32.1%), followed by C4 (28.6%) and C2 (26.4 %) (P = <0.001). Stages C5 and C6 had a lower representation, of 6.4% (P = 0.047).

After classifying the patients according to the PASI score, most of the patients included in our study fall into the moderate-severe type of the disease (61.4%), followed by the moderate type (20.7%). The severe (11.4%) and mild (6.4%) types had lower percentages. Regarding other forms of psoriasis associated with CVD, we noticed that the pustular type had the highest prevalence, being diagnosed in 3.6% of patients, followed by guttate and inverted types, with a prevalence of 2.9% and 2.1%, (P = <0.001).

TABLE I.

Chronic venous disease prevalence by age and gender

		Gender				
		Female		Male		
		N	N %	N	N %	p- value
Age	18-35	39	23.4%	28	13.5%	0.040
	36-60	68	40.7%	101	48.6%	
	over 60	60	35.9%	79	38.0%	

TABLE II
Characteristics and risk factors of patients diagnosed with chronic venous disease and psoriasis vulgaris

Parameter	N (%)	P-value	Parameter	N (%)	P-value
Gender			Environment		
• female	63 (45%)	0.041	• Rural	62 (44.3%)	0.041
• male	77 (55%)	0.055	• Urban	78 (55.7%)	0.033
Age	60,06±12,35	0.027	Severity of psoriasis		
CEAP C categories			Moderate-to-severe	86 (61.4%)	
• C2	37 (26.4%)	<0.001	Moderate	29 (20.7%)	
• C3	45 (32.1%)	<0.001	Severe	16 (11.4%)	
• C4	40 (28.6%)	<0.001	Mild	9 (6.4%)	
• C5	9 (6.4%)	0.047	PASI <10	123 (87.9%)	0.043
• C6	9 (6.4%)	0.047	PASI 10-20	12 (8.6%)	0.068
Obesity	27(19.2%)	<0.001	PASI >20	5 (3.6%)	0.055
• grade I	7 (5%)	0.012	DLQI <10	117 (83.6%)	0.001
• grade II	16 (11.4%)	0.009	DLQI 10-20	19 (13.6%)	0.033
• grade III	4 (2.9%)	0.029	DLQI >20	5 (3.6%)	0.074
Other types of psoriasis			Hypertension	66 (47.1%)	<0.001
• Guttate	4 (2.9%)	<0.001	Diabetes mellitus	19 (13.6%)	<0.001
• Inverse	3 (2.1%)	<0.001	Smoking	34 (24.3%)	<0.001
• Pustular	5 (3.6%)	<0.001			

From first figure we can observe that the moderate-severe forms of Psoriasis are mainly associated with CEAP C3 (19.3%) and C4 (17.1%), the moderate type is associated with class C3 (8.6%) and C2 (7.1%) predominantly. The severe type is associated especially with the C4 class (5.0%) and the mild type is especially associated with the C2 class (2.9%), (P = 0.099).

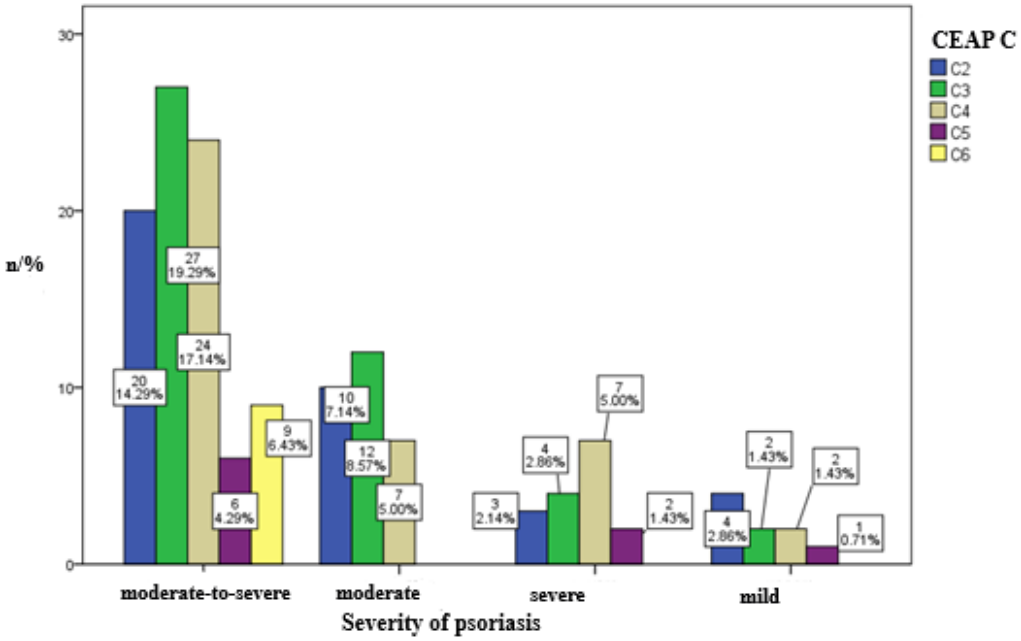

Fig. 1. Distribution of the severity forms of CVD on the severity of Psoriasis.

DISCUSSION

Compared to the experience of other medical centers, we can consider that in our study, the prevalence of chronic venous disease among the psoriatic population is high. A study conducted at the Sibiu Dermatology Clinic, during 2010-2013, on a cohort of 270 patients diagnosed with psoriasis, CVD prevalence was 22.22% (16). In another study conducted in Tunis, published in 2019, evaluating a cohort of 163 patients diagnosed with Psoriasis, the prevalence of CVD was 1% (17) There are, however, few studies published in the literature on this association. The highest prevalence of venous disease was in the age group 36-60 years, followed by the age group over 60 years. Women have a higher prevalence compared to men in the age group 18-35 years, and males have a higher prevalence in the age groups 36-60 years and over 60 years. Most patients included in the study have mild to moderate forms of venous disease. Psoriatic lesions cause the patient to consult a dermatologist, thus facilitating the early diagnosis and treatment of venous disease.

There are common risk factors involved in the etiopathogenesis of psoriasis and chronic venous disease (CVD) (1, 18). Excess body weight can trigger or maintain psoriasis or venous disease. Adipose tissue acts as an accessory endocrine organ, synthesizing over 700 peptides with a proinflammatory or metabolic role, called adipokines. Leptin, an adipokine involved in regulating appetite but also in perpetuating systemic inflammatory syndrome, has elevated serum values in psoriatic

patients (19). Other molecules involved in the onset of psoriasis are Tumor Necrosis Factor α (TNFα), Interleukin-6 and Interleukin-1 (1, 10). Obesity is also a risk factor for CVD. Recent studies show that elevated body mass index values are associated with more severe forms of venous disease (10, 13). In vivo, obesity is associated with decreased venous tonus in animal studies (11). In our study, we found a high prevalence of obesity, 19.2% of patients associated a BMI> 30 kg/m^2 (statistical value is highly significant, P = <0.001). Vlajinac *et al.* conducted a study on a group of 1116 patients diagnosed with CVD, and 15.8% had associated obesity (20). In a study of a group of psoriatic patients, Jacobi *et al.* found a prevalence of 27.6% in obesity (21). We can consider that in this study this association is also verified.

Smoking has been demonstrated as a risk factor for both psoriasis and chronic venous disease (18, 22). A meta-analysis study showed that among smokers or ex-smokers there is an increased prevalence of psoriasis. Smoking is responsible for the development of a chronic proinflammatory status and is especially associated with pustular forms of psoriasis (18). The number of packs/years is directly proportional to the severity of psoriasis. For CVD, smoking is a risk factor in young patients (<35 years) and especially in males (23). Gourgou *et al.* demonstrated that the appearance of varicose veins is closely related to the number of cigarettes consumed per day (24). In this study, 24.3% of patients are smokers or ex-smokers. Adışen *et al.* conducted a study on 563 patients diagnosed with plaque psoriasis between 2007 and 2013, and the prevalence of smoking in this population was 50.1% (25). Regarding the association of smoking with CVD, Gourgou *et al.* conducted a study on 1806 patients with venous disease and the prevalence of smoking in this group was 37% (24).

Cardiovascular comorbidities are associated with both psoriasis and venous disease. Psoriatic patients, especially those with severe forms, have an increased prevalence of hypertension (26). On the other hand, hypertension is a risk factor involved in the onset of psoriatic disease, as demonstrated in the study performed by Kim *et al*. in 2018, in which hypertensive patients had an increased incidence of psoriatic disease (12). Criqui *et al*. found that elevated blood pressure, both systolic and diastolic, is associated with chronic venous disease (22). A study conducted in Catalonia on a population of psoriatic patients, concluded that the most common comorbidities of psoriasis are hypertension and type II Diabetes, with prevalences of 34.4% and 14.7% (27). In our study, the prevalence of hypertension was high, with a value of 47.1%, and diabetes mellitus had a prevalence of 13.6%. Psoriasis is a risk factor for the onset of type II diabetes, regardless of age or disease severity (18). Diabetes mellitus may be considered a comorbidity in the patient with CVD. The vascular pathological changes induced by chronic hyperglycemia are represented by endothelial dysfunction, reduced peripheral perfusion and local angiogenesis (13).

CONCLUSIONS

Both psoriasis and chronic venous disease are common pathologies in dermatological medical practice, both of which have a negative impact on the patient's quality of life. In this study, the prevalence of CVD among psoriatic patients was significantly higher than the worldwide published results. There are, however, very few studies that have included this association.

In this population, there is a statistically significant high connection with hypertension, diabetes, obesity and smoking. Considering the results of our study, we consider that it is necessary to deepen this topic in future studies.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest and they received no funding.

CHALLENGES OF IMPLEMENTATION OF A FAST-TRACKED PRE-HOSPITAL POCUS ROUTINE (Abstract): The COVID-19 pandemic has changed the way of care for our patients and for our staff, many departments have compared the pandemic period to a 4 yearlong mass casualty situation managing scarce resources with insufficient manpower in a constantly shifting environment. A major bottleneck for healthcare systems were imagistic studies and the constant need for it, a foundation of modern medical practice. With the aim to improve care and facilitate better decision making we introduced a portable ultrasound device to the pre-hospital team, after providing Point of Care Ultrasound workshops to practicing physicians. **Materials and methods:** We performed a prospective observational study over 6 months, during the height of the COVID pandemic, using the extended Focused Assessment Sonography in Trauma (eFAST) protocol and the Shock Index (SI) to understand patient status; voluntary sampling was done by emergency physicians. The final outcomes were patient numbers, severity and type of cases and usage trends. **Results:** the study registered 34 patients: 41% traumas, 35% cardiac arrests, 18% shock, 6% acute respiratory distress. **Conclusions:** The overall increase and necessity of POCUS use during the pandemic or other mass casualty incidents does not equate to competency or familiarity of use despite workshops, instruments and willingness. Adapting and improving implementation of any new techniques requires a mature and professional team willing to collaborate, establish transparent feedback loops and implementation programs catered to the local needs. In this article we discuss the benefits and flaws we identified from a direct approach. **Keywords:** EMERGENCY, FAST-TRACKED PRE-HOSPITAL, POCUS, ROUTINE.

Imagistic input is a staple of modern medical investigation, diagnosis and treatment but with high convenience comes a high vulnerability in critical times such as mass casualty situations or pandemics. One of the first evocative, and dramatic, experiences of modern casualty management was during the 1988 earthquake in Armenia that had over 150000 victims and over 25,000 deaths, imagistic triage was accomplished

with 30 ultrasound scanners and one computer tomography machine (1). Romania has a symbiotic relationship with radiology while providing patient care (2) but with an ever-increasing reliance on advanced imagistic techniques to evaluate patients with critical illness, fatigue was evident in the radiology team and a way to quickly assess but also triage the need for future imagistic investigations needed to be adopted. In late 2020 following one year of pandemic experience, we added a portable ultrasound device to the pre-hospital phase, the GE Handheld VSCAN Dual Probe (General Electric Company, New York, USA), to help physicians provide better patient care and help with decision-making under difficult conditions due to pandemic fatigue and limitations imposed by personal protective equipment (PPE).

MATERIALS AND METHODS

Study Aim: Study how a fast-tracked implementation of ultrasound workshops influences emergency physician use of Point of Care Ultrasound in pre-hospital. We provide emergency physician pre-hospital teams with specific training and an ultrasound machine to improve critical patient diagnosis and management before arrival at the hospital.

Study Setting. A prospective observational study with voluntary sampling submitted by emergency physicians that are performing pre-hospital shifts on the Mobile Intensive Care ambulance (MIC) during the COVID-19 pandemic. The study was done one year after the introduction of the ultrasound machine to the ambulance.

The submitting physicians had previously participated in at least one Point of Care Ultrasound Workshop that was done with support from the European Society of Emergency Medicine (EuSEM). The workshops were structured over a two-day teaching period with multiple working stations focused on participant scanning experience and scan time. Workshop covered ultrasound basics, extended Focused Assessment Sonography in Trauma (eFAST), aorta lung and cardiac views.

The MIC ambulance is sent to cases in various environments following initial calls to 112 that meet the requirements for potential life-threatening situation, in support to lower ranked ambulances that require assistance or to facilitate intra-hospital transfer of critical patients. The environment can present different levels of accessibility difficulty, and at times can be at considerable distances from the closest hospital due to local geographical features and hospital placement making field decisions (stay and play approach) even more important.

The study took place in the county of Iasi, Romania, between January and June 2022, with ethics commission approval number 147/31.01.2022 from the "Grigore T. Popa" University of Medicine and Pharmacy Iasi and the "Sf. Spiridon" County Clinical Emergency Hospital from Iasi ethics commission board – The ethics approval was a part of a larger study.

Study Design

Participating physicians were instructed to complete a standard report form detailing patient demographics, cardiovascular parameters, causes for examination, ultrasound findings, diagnosis, elapsed time from arrival of crew till hospital transport and difficulties encountered. The encouraged scanning protocol was eFAST but pinpoint observations were also openly accepted.

Data Collection

The reporting physician gathered all the information required and submitted it

anonymously.

Data Analysis

Shock Index was calculated after data submission to quantify hemodynamic status. The cases were divided in 4 groups: shock, acute respiratory distress, cardiac arrest and trauma depending on presenting motive, positive findings were noted, elapsed time from crew presentation till hospital arrival, and final diagnosis.

Descriptive data analysis was performed.

RESULTS

The starting point for the study was 2019, when POCUS was not performed in our Emergency Department by emergency physicians, due to ease of access and close collaboration with the radiology department for diagnostic ultrasonography and advanced imaging (2).

The total number of participating physicians was 23 and the total number of cases submitted was 34. Emergency physicians preferred to use ultrasound with the following types of cases: 6 with shock, 2 with acute respiratory depression, 14 with trauma and 12 with cardiac arrests. The age varied between 18 and 81 years with an average of 57 and a ratio of female to male of 2.1:1. Shock Index was above 0.75 in 14 cases out of 22.

TABLE I
Categories of patients' groups

Category	Patients	Shock Index > 0.75	Causes/initial examination	US Findings
Overall	34	14		19 Positive findings
Shock	6	4	2 Undifferentiated, 2 Septic, 4 Cardiac,	4 Hypokinesia, 2 RV Strain
Trauma	14	8	12 Road Traffic Accidents, 2 Falls from Height	6 Free abdominal fluid, 2 Pneumothorax
Cardiac Arrest	12	N/A	8 Asystole, 2 PEA, 2 VT/VF	3 Mechanical activity, 2 RV strain
Acute Respiratory Distress	2	2	N/A	N/A

The **shock group** had a total of 6 patients out of which, 2 had an undifferentiated shock, 0 presented as septic, 4 had a cardiogenic shock and none presented with obstructive shock. A Shock Index of >0.75 was identified in 4 patients. Ultrasound findings reported were positive in 4 patients with hypokinesia and 2 with right ventricle (RV) strain.

The **group** with **acute respiratory distress** numbered 2 patients both with a SI > 0.75 but with no significant findings on ultrasound scans.

The trauma group numbered 14 patients, 12 were due to road traffic accidents and 2 fell from height (more than two meters). From the 14 patients with trauma, 8 patients had a SI >0.75. eFAST scans were done and 6 patients were found positive for abdominal free fluid and 2 for pneumothorax.

The cardiac arrest group numbered 12 patients that had as initial rhythm as fol-

low, 8 with asystole, 2 with pulseless electrical activity and 2 with Ventricular Fibrillation or Ventricular Tachycardia. On ultrasound scan during CPR 3 patients were found to have mechanical activity 2 of which presented Right Ventricle strain.

The following difficulties while performing ultrasound in pre-hospital were reported by operators: 7 cases were difficult to exam/obtain images due to body status, 2 were very agitated, 1 due to extremely low ambient temperature and 1 due to patient lodged foreign body and the way he/she was immobilized in a patient from road traffic crash.

The following data was excluded from the data presented due to inconsistencies in submissions: The time elapsed at the scene and the time of arrival at the hospital. Accuracy of findings was not possible as follow-up was not completed due to multiple factors described in the discussion subheading.

DISCUSSION

The COVID pandemic challenged the way we practice medicine and the way we implement new techniques and habits into daily practice due to a constant struggle to reduce risk of infection for both patients and staff with several rushed decisions having to be made to cope with new patient influx and adjust to current working realities.

A lot of suspected COVID patients were investigated at the start of the pandemic by computer tomography (CT); drastically increasing the rate of non-contrasts scans (4). Although a shift from early CT assessment was done, usage remained high due to an increased risk of COVID patient population complications such as pulmonary embolism or co-infections. CT was also recommended to patients with an initial negative RT-PCR but a high suspicion of severe infection especially in environments with limited test in (5, 6, 7). Alongside the influx of COVID infections, non-COVID medical and surgical patients had diagnostic, management and treatment requirements that needed radiology input. Overall, this contributed to a tremendous stress on the radiology department and increased waiting times in some already standstill emergency departments.

The high workload was taking a toll the medical personnel and already in 2020 reports were coming out stating that 46% of radiologists were burned out compared to the average of 42% in all other specialties due to workload, complexity of cases, constant change of schedule and longer time between scans due to decontamination measures (8, 9).

As the pandemic progressed, technology started to step in and relieve pressure from repetitive tasks. Deep learning models were implemented to help analyze chest x-rays and chest CT obtaining a sensitivity of 92.3% and specificity of 85.1% for CT at the start of the pandemic progressing to a sensitivity of 97.6% and specificity of 78.6% with chest x-rays, but this was not available everywhere (10, 11, 12). Lung ultrasound such as the BLUE protocol (13) is seen as a viable way of imaging patients with accuracy rates comparable to CT or X-rays (14-17) but with obvious limitations in the form of required user experience.

The decision to initiate advanced imaging requests is directed by physicians, and with a high workload, decision fatigue was high. The choice to develop POCUS protocol use within our department was appropriate, especially since steps to develop a POCUS program was underway prior to the pandemic. The goal was to relieve pressure

from the radiology department by optimizing patient evaluation and provide the means of getting the required simple, straightforward answers needed in most cases. The goal of POCUS has always been that of answering simple but important questions at the right time to provide clarity to the attending physician (18).

The workshops we provided are supported by experienced POCUS providers from the European Union Society of Emergency Medicine (EUSEM) and started two years prior to ultrasound introduction to the ambulance crew. They were geared to provide participants with the maximum scanning time and patient experience within the two days of the workshop, covering different topics and learning goals. Initial enthusiasm was high for the first workshop in the first half of 2019, before the pandemic, and during the second one, that took place in 2021 in the middle of the pandemic. The introduction of an ultrasound machine to the ambulance was also meet with great enthusiasm and seen as a breath of fresh air in a very difficult environment due to epidemic restrictions, high patient load and personal protective equipment (PPE).

The study was started one year after the introduction of ultrasound to the pre-hospital, to have a better idea of trends and usage. The initial enthusiasm did not carry well to practice, at least when translated into submitted cases for the study. The meager 34 properly submitted cases did not meet surveyor expectations but the reasoning behind it provided valuable information on local learning requirements and characteristics.

The lack of cases submitted was partly explained by 1) the fact that POCUS was not considered to be of use in all encountered cases and 2) when faced with critical cases that would have benefited from POCUS but required fast actions, most doctors preferred to fall back on ingrained behavior from Advanced Life Support or Advanced Trauma Life Support protocols without utilizing POCUS due to feelings of inadequacy from lack of experience with ultrasound.

Participants also declared that ultrasound was used a lot more than the submitted cases but due to long mission times, downtimes due to decontamination or back-to-back missions, information was omitted and not submitted to not pollute results.

The main request from most of the participants was more workshops or even implementation of POCUS curricula for residents, where even established physicians could participate. This led us to further implement an expansion of POCUS teaching intro actual clinical practice to stress its usability in critical situations. These aspects have been studied and detailed in another study, performed and published by the authors (18). Without guidance and experience sharing the risk of inconsistent results or wrongful use is high and this in turn makes it dangerous for the operator to trust in the gained skills but also for them to practice in a wrong or inefficient manner.

Experience gathered during this period, can easily be applied to future mass casualty situation or other pandemics that may or may not come, solidifying the importance of adaptability and agility.

Documentation is a normal part of daily medical life, especially in pre-hospital where every step, procedure, medication and detail need to be noted to ensure safety of all parties. A severe disruption in effective documentation was noted during the heights of the pandemic, due to a multitude

of factors such as: personal protective equipment, sterilization protocols for ambulances and equipment, translating into long down-times and sometimes inability to maintain correct medical documentation. (19) An important limitation of our study was the lack of integration of data from the ultrasound machine to safe localized data storage and thus a heavier reliance on human scribing and submitting.

An implementation of the lessons learned in this study with the addition of easier to use and automate reporting mechanisms would provide a better understanding of POCUS usage and changes required to improve teaching and study protocols for future research.

CONCLUSIONS

Implementing correct and confident POCUS use in the daily practice of acute high paced departments cannot be achieved by providing ultrasound workshops. These will provide respite in resource strained environments but in the case of patients that require fast decisions, seldom will care providers, with just workshops experience, use these skills effectively in their evaluation and care, falling back to ingrained behavior or risk misusing said skills. The lessons learned from adapting to difficult conditions such as those created by the pandemic are that we need to cultivate flexibility and adaptability, both of which are characteristics POCUS. Creating the prerequisites for a POCUS training curriculum would provide better current care and better resistance in the event of future mass casualty situations.

ACKNOWLEDGEMENTS

Studies such as these would be impossible without the constant support from the whole staff, residency and clinical leads that always advocate for further development of education and training.

CONFLICT OF INTEREST AND FUNDING

This study benefited from no outside funding and no conflict of interests are reported

LUNG DAMAGE IN RHEUMATOID ARTHRITIS - A PROSPECTIVE ANALYSIS (Abstract): The objective of this prospective study was to make correlations between demographic and rheumatoid arthritis (RA)-related characteristics and the type and severity of the interstitial lung involvement (ILD), being able to quantify a potential "gold standard" in predicting the development of these extra-articular manifestations (EAMs) that worsen the disease and increase the morbidity. **Materials and methods**: 60 RA patients were included in the analysis over a period of 2 years and the following data were centralized: demographic characteristics, the presence of lung damage quantified by pulmonary high-resolution computed tomography (HRCT), the presence of specific RA antibodies (anticitrullinated peptide antibodies - ACPAs), duration and activity of RA, pulmonary function measured by diffusing capacity for carbon monoxide (DLCO). Using different statistical tests, we analyzed the correlations between these parameters, trying to highlight the possible risk factors involved in the appearance of pulmonary manifestations in RA. **Results:** We included in our prospective study 60 patients, mostly women (n=46; 76.7%) with a mean age of 63.02±10 years old and with a mean age of disease onset of 51.89 years (95% CI: 48.86 to 54.93). Out of the 60 cases, data on smoking status was available for 34 participants, 82.4% being non-smokers, while 17.6% having an active smoker status. Regarding pulmonary function tests, 60% of the patients showed a decreased DLCO. More than half of the subjects (63.18%) had increased values of ACPAs. The results obtained were promising, demonstrating a direct relationship between both the DLCO decrease and the presence of specific ACPA antibodies, as well as between the appearance of lung-specific changes on HRCT and the increased titer of ACPAs. Also, the decrease in lung function was correlated with the radiological manifestations highlighted on HRCT. **Conclusions:** The presented study supports the close relationship between AR and ILD, pointing out the need for a careful pulmonary evaluation in these patients. The more active the disease, the higher the risk of developing lung damage. An early diagnosis and an adequate treatment can improve the prognosis of these patients. **Keywords**: RHEUMATOID ARTHRITIS, INTERSTITIAL LUNG DISEASE, DIFFUSING CAPACITY FOR CARBON MONOXIDE, ANTICITRULLINATED PEPTIDE ANTIBODIES.

INTRODUCTION

RA is a systemic autoimmune condition which has a vast panel of EAMs, interstitial lung disease being one of the most frequent and problematic EAMs due to an unfavorable prognosis and a delayed diagnosis. RA-

ILD is a multifaced disease, in which the ACPAs play a key role (1, 2). Being first described in 1948 by Ellman and Ball (3), ILD is much more common nowadays. The prevalence of ILD in RA patients may vary between 5-67% (4, 5). The women are more predisposed to the disease (6). The disease does not respect a certain pattern, any segment of the lungs compartment can be involved. The etiology of RA-ILD is yet not fully elucidated. The presence of ACPAs can precede the disease onset with many years (7-11).

The main steps in the diagnosis of RA-ILD are represented by an impairment of pulmonary function (mainly a decrease value of DLCO), a specific lung pattern highlighted by HRCT, and an active disease characterized by an inflammatory status and a high disease activity determined by the Disease Activity Score in 28 joints-C-reactive protein (CRP)(DAS28-CRP). The later the onset of the disease is, the more preserved the prognosis can be (12-14). HRCT scan represents the main tool in the diagnosis of ILD. There are two most frequent and specific patterns in RA-ILD: usual interstitial pneumonia (UIP) in 40-60% patients, named "temporal heterogeneous pattern" and non-usual interstitial pneumonia (NSIP) which can appear in 10-30% patients, named "spatial homogeneous pattern". UIP illustrates a symbiosis of lung fibrosis areas combined with healthy pulmonary tissue having a distribution in subpleural sites and being characterized by the "honeycombing" aspect. In contrast, NSIP has a bilateral distribution, usually in the inferior lobes, known as "ground-glass opacities" and bronchiectasis (15-18).

MATERIAL AND METHODS

RA-ILD patients (n=60) attending Rheumatology department of Clinical Rehabilitation Hospital, Iasi, Romania from august 2022 to august 2024 were enrolled in this prospective study. The patients were diagnosed using 1987 ACR or 2010 ACR/EULAR classification criteria. The inclusion criteria were a positive diagnosis of RA according to the classification criteria, a signed informed consent, and age more than 18 years old. The exclusion criteria were age under 18 years old, the presence of an Overlap syndrome, active infections, neoplasms, severe comorbidities (hepatic, cardiac, or renal involvement), and non-adherence to treatment.

The objective of our study was to highlight the correlations between different parameters of RA and the type and severity of the lung involvement. In the patient's medical records, the following data were included: demographic characteristics, the presence of lung damage quantified by HRCT, the presence of specific RA antibodies (ACPAs), duration and activity of RA, pulmonary functionality measured by DLCO. There was no restriction on the use of any conventional synthetic disease-modifying antirheumatic drugs (csDMARD) or biological therapy.

After collecting these data and using different statistical tests, we analyzed the correlations between them in order to highlight some possible risk factors for the development of pulmonary manifestations in RA.

The disease activity was measured using the DAS28-CRP score. Recent studies highlighted that CRP is more specific for RA-ILD, than erythrocyte sedimentation rate (ESR). The seropositivity, especially the presence of ACPAs was evaluated using Alegria device by an enzyme-linked immunosorbent assay (ELISA), a robust and sensitive technique. High titers of ACPA were considered those over three times

the normal value (N:0-20 U/mL). The functional lung tests were accomplished in accordance with the standards in force. We took into consideration the value of DLCO, and we included only the percent of predicted values of DLCO. All patients underwent a pulmonary HRCT. Patients who had traction bronchiectasis, reticular abnormalities, a basal distribution, "honeycombing" aspect or "ground glass opacification" were included, having a characteristic aspect for RA-ILD.

Statistical analysis

The data analysis was conducted using *SPSS version 26.0* statistical software. Descriptive statistics were presented as means (M), standard deviations (SD), and percentages (%). For continuous variables with a normal distribution, the mean (M) and standard deviation (SD) were used, while non-normally distributed variables were described using the median and interquartile range (IQR). Group comparisons were performed using chi-square tests (χ^2) for categorical variables, with Fisher's exact test applied when expected frequencies were below 5. For continuous variables, independent samples t-tests or Mann-Whitney U tests were utilized, depending on the data distribution. Kendall's tau-b correlation coefficient was used to analyze associations between continuous variables, such as DLCO, Age, and ACPA. All tests were two-tailed, with statistical significance set at $p < 0.05$, except where noted (e.g., marginal significance at $p < 0.10$). Abbreviations used include M (Mean), SD (Standard Deviation), IQR (Interquartile Range), CI (Confidence Interval), t (t-test statistic), χ^2 (Chi-Square statistic), p (p-value), N (Sample Size), and OR (Odds Ratio).

RESULTS

60 RA-ILD patients met the criteria for the inclusion in the study. The median age of the patients was 64.5 years. The demographic and RA-related data are presented in the first table.

TABLE I.

Demographic and RA-related characteristics of patients.

Characteristics	N=60	%
Gender		
Male	14	23.3%
Female	46	76.7%
Median age	64.5±10 years	
Smoking history		
Yes	6	10.0%
No	28	46.7%
Seropositivity		
Yes	49	81.7%
No	11	18.3
Disease activity (DAS28-CRP)		
Low	29	48.3%
Moderate	21	35.0%
High	10	16.7%
HRCT		
Specific pattern	43	71.7%
No specific pattern	17	28.3%
DLCO		
Normal values	24	40.0%
Decreased values	36	60.0%

Of the 60 cases, 23.3% were male and 76.7% female. The average age of males was 62.93 years (95% CI for Mean ranges from 56.50 to 69.36) and the average age of females was 63.02 years (95% CI for Mean means, the true mean age of females in the population is likely between 59.93 and 66.11 years). The age distribution for both males and females is symmetrical, with similar means and medians.

Data on smoker status were available only for 34 subjects. Among those with valid data, 82.4% reported being non-smokers, while 17.6% reported being active smokers. Non-smokers had a mean age of 65.04 years with a 95% CI ranging from 60.67 to 69.40 years and a median of 66.5

years. In contrast, smokers had a lower mean age of 61.33 years (95% CI: 54.67 to 67.99) and a median of 62 years.

In the studied group, 81.7% of cases were seropositive. Out of the 60 patients, 23.3% had ACPA levels below the normal value of 20. 6.7% had ACPA levels 4-5 times higher than normal range (80-100), while 16.7% had ACPA values exceeding 80-100. A significant 18.3% of individuals had ACPA levels at or exceeding 1000 (tab. II).

TABLE II.

The ACPAs values in seropositive patients.

ACPA	Frequency	%	Valid %	Cumulative %
Below normal (**<20**)	14	23.3%	35.0%	35.0%
4-5 times higher than normal (**80-100**)	4	6.7%	10.0%	45.0%

For seronegative individuals, the mean age was 62.18 years (95% CI: 55.95 to 68.42), with a median of 65 years. For seropositive individuals, the mean age was slightly higher reaching to 63.18 years (95% CI: 60.08 to 66.28), with a median of 64 years. Overall, seropositive individuals exhibited higher age variability with a more balanced distribution, while seronegative individuals had a more concentrated age range with a noticeable skew towards younger ages.

Out of the total 60 patients, nearly half (48.3%) had a low Disease Activity Score (DAS28-CRP), 35% had a moderate disease activity, and 16.7% were categorized as having high disease activity. For the low disease activity group, the mean age was 64.10 years (95% CI: 59.68 to 68.53), with a median of 65 years. For the moderate disease activity group, the mean age was slightly lower at 63.86 years (95% CI: 59.69 to 68.03), with a median of 65 years. For the high disease activity group, the mean age was decreased at 58.00 years (95% CI: 51.65 to 64.35), with a median of 62 years. Overall, as disease activity increases, the mean age tends to decrease, and the variability in ages becomes slightly more constrained (fig. 1).

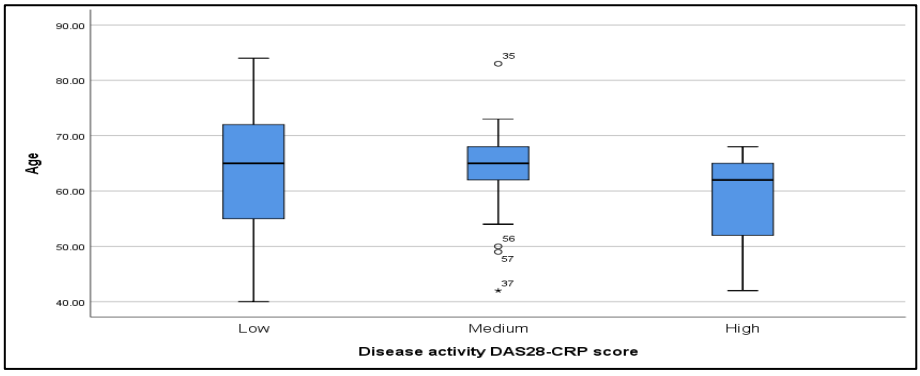

Fig. 1. The mean age regarding disease activity.

Out of the 60 subjects, the majority (71.7%) showed a specific pattern on HRCT, while 28.3% did not exhibit any specific pattern. For individuals who did not have a specific pattern on HRCT scan, the mean age was 60.24 years (95% CI: 54.57 to 65.90), with a median of 63 years. In contrast, individuals with a specific pattern on HRCT scan had a higher mean age of 64.09 years (95% CI: 60.96 to 67.23), with a median of 65 years.

Regarding functional lung tests, 60% cases exhibited a decrease in DLCO, while 40% had normal DLCO values. For individuals having a normal DLCO, the mean age was 59.79 years (95% CI: 55.57 to 64.01), with a median of 62 years. For individuals with a decreased DLCO, the mean age was 65.14 years (95% CI: 61.63 to 68.65), with a median of 67 years. Among the 36 cases having a decreased DLCO, 83.3% were seropositive, and 16.7% were seronegative. As a percentage of the total sample, 50% of the participants had both a decreased DLCO and were seropositive, while 10% had a decreased DLCO and were seronegative. Most individuals having a decreased DLCO were seropositive, suggesting a strong association between seropositivity and a decreased lung function.

The mean age of disease onset was 51.85 years (95% CI: 49.15 to 54.55), with a median of 52 years. For males, the mean age of disease onset was 51.71 years (95% CI: 45.02 to 58.41), with a median of 50.5 years. For females, the mean age of disease onset was 51.89 years (95% CI: 48.86 to 54.93), with a median of 52 years. For seronegative patients, the mean age of disease onset was 49.91 years (95% CI: 45.12 to 54.70), with a median of 52 years. For seropositive patients, the mean age of disease onset was slightly higher 52.29 years (95% CI: 49.10 to 55.47), with a median of 52 years. Overall, while the median ages were similar, seropositive individuals showed more diversity in the age of disease onset. For patients having a low disease activity, the mean age of onset was 53.03 years (95% CI: 48.51 to 57.56), with a median of 54 years. For individuals with a moderate disease activity, the mean age of onset was 50.48 years (95% CI: 46.09 to 54.86), with a median of 52 years. For the cases having a high disease activity, the mean age of onset was 51.30 years (95% CI: 45.74 to 56.86), with a median of 51.5 years. Overall, as disease activity increased, the age of disease onset showed less variability.

The crosstabulation analysis between DLCO and ACPAs presence showed that among the 24 patients having a normal DLCO, 5 patients (45.45%) were seronegative, and 19 patients (38.78%) were seropositive. In contrast, among 36 patients having a decreased DLCO, 6 patients (54.55%) were seronegative, while 30 patients (61.22%) were seropositive. The overall distribution indicates that a higher proportion of patients with a decreased DLCO were seropositive compared to those having a normal DLCO. This suggests a potential association between seropositivity and DLCO decline (tab. III).

TABLE III.

The correlation between DLCO and the presence of ACPAs.

DLCO	Seronegativity	Seropositivity	Total
Normal value	5 (45.45%)	19 (38.78%)	24
Decreased value	6 (54.55%)	30 (61.22%)	36
Total	11	49	60

However, The Chi-Square test assessing the relationship between DLCO (Normal *vs.* Decrease) and Seropositivity and Seronegativity yielded non-significant results. The Pearson Chi-Square value was 0.167, with a p-value of 0.683, suggesting no association between DLCO and seropositivity / serone-gativity. The Continuity Correction, applied due to small-expected counts, showed a p-value of 0.946, reinforcing the lack of significance. The Likelihood Ratio produced a p-value of 0.684, consistent with the Pearson test, while Fisher's Exact Test (appropriate for small samples) showed no significant association with a p-value of 0.741.

Analyzing the link between HRCT findings and the presence of ACPAs, we had a total sample of 60 patients; 71.7% had a specific pattern identified on HRCT scans, while 28.3% had no specific HRCT pattern. When looking at the distribution of seropozitivity, the majority of patients with specific HRCT pattern (73.5%) were seropositive, compared to only 26.5% who were seronegative. Among those without specific pattern on HRCT, 76.5% were seropositive and 23.5% were seronegative. Overall, the results suggest that patients having a specific pattern on HRCT are more likely to be seropositive. In the Chi-Square test for the association between HRCT findings and seropositivity/seronegativity, the Pearson Chi-Square value was χ^2 (1, N = 60) = 0.428, with a p-value of 0.513, indicating no significant association between the two variables ($p > 0.05$). The Continuity Correction for continuity in small samples also yielded a non-significant result ($p = 0.777$), confirming that the relationship is not statistically significant. Additionally, the Likelihood Ratio and Fisher's Exact Test provided p-values of 0.521 and 0.712, respectively, both of which support the absence of a significant association (tab. IV).

TABLE IV.
The correlation between HRCT and the presence of ACPAs.

HRCT	Seronegativity	Seropositivity	Total
No specific pattern	4 (23.5%)	13 (26.5%)	17 (28.3%)
Specific pattern	7 (41.2%)	36 (73.5%)	43 (71.7%)
Total	11	49	60

The crosstabulation between HRCT pattern and DLCO showed that among the 17 patients with no specific pattern on HRCT, 10 (58.82%) had a normal DLCO, while 7 (41.18%) showed a decrease in DLCO. On the other hand, among the 43 patients with a specific pattern on HRCT, 14 (32.56%) had a normal DLCO, while a higher proportion of 29 (67.44%) had a decrease in DLCO. Overall, in the total sample of 60 patients, 24 (40%) had normal DLCO, and 36 (60%) experienced a decreased DLCO. This distribution suggests that patients having a specific pattern on HRCT tend to have a higher likelihood of a decreased DLCO compared to those with no specific modifications. For a significance level of 10% ($\alpha = 0.10$), the Pearson Chi-Square test showed a Chi-Square value of 3.502 with 1 degree of freedom and a p-value of 0.061. Since this p-value is slightly above the conventional 5% threshold but below 10%, the result suggests a marginally significant association between the variables. The Likelihood Ratio test,
